Microscopic observations and both chemical and physical analyses of cell-membrane formation and structure have accumulated in large numbers during the past decade. Sponsler²⁴⁶ observed in *Rhizoclonium*, whose cells measure $100 \times 20\mu$, that the cross wall starts as a ring-like projection on the inside of the cell wall and grows by the addition of material on its inner edge, gradually building the ring into a solid disc. Concentric layers 0.1μ thick are said to be deposited on the inner edge of the ring at the rate of 1 layer per minute. Ritter²¹⁰ reviewed his extensive work with the disintegration of wood fibers into fibrils, fusiform bodies, and spherical units and reported,^{p. 60} "The ash residue from wood forms a continuous skeleton consisting of long, slender, tube-like filaments resembling the fibrils and having innumerable constrictions. The constrictions make the tubes appear to consist of hollow beads, each of which is attached to its two adjoining neighbors end to end and partitioned into variously shaped compartments." The author believes that a large proportion of the ash-forming substance probably exists where water can reside, in the spaces around the structural units. Brown³⁴ found that the ash residue resulting from the burning of wood fibers retains the fiber skeleton, even though it constitutes less than 1 per cent of the total fiber. Astbury, Marwick, and Bernal¹² and van Itersen¹³⁷ made important contributions to the knowledge of the wall structure of *Valonia*. Hess¹²⁵ reported that cellulose membranes are made up mostly of a crystalline substance which diffracts x-rays, surrounded by a thin sheath of another substance whose reactions to fluids determine the permeability. Morphological differentiation was shown in dark-field, in swollen material. The crystalline substance was identified as cellulose, but the "Hautsubstanz," present in very small quantities, had been neither isolated nor identified. He concluded that the recognition of these two fiber components is important for the understanding of the characteristics of fiber structure as well as for reactions to reagents. Hess, Kiessig, Wergin and Engel¹²⁷ corroborated Sisson's²³⁷ identifications of crystalline cellulose in young cotton fibers in which unextracted and chloroform-extracted cotton fibers did not show the cellulose diagram. It appears first after extraction with hot or cold water. An unknown substance which is removed by water extraction evidently masks the x-ray diagram. Goncharov and Burvasser⁸⁸ report that along with pure cellulose there are very thin

films surrounding every structural element of the fiber. Their percentage in the fiber is very small, but they greatly affect its properties. Lüdtke¹⁵⁹ commented that many errors arise in the interpretations of the structure of plant fibers by placing too much weight upon the results of a single method, and that x-ray diffraction and

microscopic analyses should be supplemented by microchemical tests in order to give a true picture of the identity and position of the components of the cell wall. Staudinger and Reinecke²⁵¹ reported a study of the degree of polymerization of celluloses in old fabrics. All cellulose with a value less than 200, as determined by viscosity measurements, had lost its characteristic property of forming fibers, and although degraded was not chemically changed. Farr⁵⁹ reported that the cellulose component of the cell membrane of the cotton fiber, which is in the form of diminutive cellulose particles, does not dissolve in the standard solution of cuprammonium hydroxide specified by the American Chemical Society to produce the viscosities commonly attributed to them. The fiber is transformed by the cuprammonium hydroxide into a swollen, viscous mass of cementing material in which the cellulose particles are dispersed. These results were corroborated by Sisson²³⁹ by means of dispersion, electrokinetic and coagulation studies, and by Compton⁴² through viscosity and slit ultramicroscopic determinations. Wergin²⁶³ made visible the existing homogeneities of the cell wall by swelling it with cuprammonium hydroxide, and thus identified the fibrils which, in turn, separated from a string-of-pearl arrangement into small (0.25μ) cellulose particles. Roberts and Haring²¹¹ showed the presence of a row of cellulose particles in the cross walls of the protenema of *Polytrichum commune*. Kerr¹⁴¹ reported that the wall of the cotton fiber is a continuous matrix of cellulose, some portions of which are denser than others. The lamellated appearance of the swollen wall is considered to be due to alternations of dense zones of cellulose with zones in which the cellulose is much less dense, larger quantities being deposited during the day than at night, because of temperature changes. Anderson and Moore¹¹ reported that cotton fibers grown under continuous artificial light have no growth rings in their walls. Collenchymatous cell walls in the same plants show characteristic lamellations. Barrows,²⁰ in a study of the cross-sectional structure of cotton fibers grown in both continuous and intermittent light, found no relation between lamellate structure and the daily periodicities. Lamellae are always present, but vary so greatly in number from fiber to fiber on the same seed and from base to tip on the same fiber that no evidence of daily "growth rings" could be found. Bailey and Kerr¹⁶ reported that the cellulose matrix of the swollen secondary wall of cotton fibers and of certain lignified cell membranes is an extremely heterogeneous but firmly coherent structure, the finer details of which grade down to the limits of microscopic visibility. I. W. Bailey¹⁵ found that both primary and secondary walls of typical cells of the higher plants are composed of a porous but firmly coherent matrix of anisotropic cellulose, whose finer structural details likewise grade down to the limits of microscopic visibility, i.e., 0.1μ or less. Lignin and other non-cellulosic constituents may be deposited in the elongated, intercommunicating interstices of the cellulose, thus resulting in two continuous, interpenetrating systems. A. J. Bailey and Brown¹⁴ found the fibrils of wood fibers to be made up of single rows of cellulose particles approximately 1 micron in size and held together by an amorphous matrix. Anderson and Kerr¹⁰ reported two spiral systems of cellulose making an angle of approximately 70° with the long axis of the fiber in the walls of 2-day-old cotton fibers; the cellulose in the primary wall was seen to form an open meshwork of fine thread-like strands that frequently anastomosed; the secondary lamellae are composed of dense and less dense areas of cellulose, the layers being formed of systems of spirally wound branching threads; in 5-day-old fibers *plastids* containing starch were seen throughout the cytoplasm; in 9-day fibers they had increased markedly in size and prominence. Hess,¹²⁶ as a result of chemical, microscopic, and x-ray studies, reported that between the fibrillae in a fiber wall lies an easily affected substance which appears in the microscope as a gelatinous material. When treated with swelling agents the fibrils break down into particles which are not exactly spherical, but are elongated in the direction of the fibril axis. In dark-field they measured 0.2μ in diameter. Heuser and Green¹³⁰ treated wax-free cotton fibers with

0.5 per cent and 2 per cent ammonium oxalate in the air and in a nitrogen atmosphere at 70 to 80° C for 600 to 3000 hours. In all cases the fibers emerged from the treatment physically undamaged. The existence of a *cementing substance* in the fiber as a fundamental constituent was rendered improbable and the cupran ammonium viscosity of a solution of the fibers was found to be a property of the entire fiber and not of a problematical cementing material alone. Whistler, Martin, and Harris²⁶⁶ found that cotton freed of pectic substance with alkali showed no significant change in tensile strength or in viscosity. Conversely, cupran ammonium solution to which pectic material from various sources had been added substantiated this conclusion. Whistler, Martin, and Harris²⁶⁵ described a new method for measurement of uronic acids in cellulose membranes. Some of the recent reviews of various phases of plant-cell membrane analysis which have appeared are by Norman,¹⁹⁰ Heuser,¹²⁹ Preston,²⁰² Stiles,²⁵³ Nickerson,¹⁸⁷ and Kratky.¹⁵¹ Studies dealing with the relation of cell-membrane structure to cell elongation in the living plant have been published by Ruge,²¹² Heyn,¹³¹ Preston,²⁰¹ and Farr and Sisson.⁶⁵

The most comprehensive microscopic study of the formation and structure of plant-cell membranes which has appeared during the present decade is that of Wieler.²⁶⁷ In many tissues from a large number of plants from all parts of the plant kingdom, he has followed the important function performed by the outer portion of the protoplast in organizing the secondary lamellae of the cell membrane. In the fresh tissues this viscous film is quite conspicuous, and Wieler expresses surprise that it has remained unnoticed in the researches made during the last years by Frey-Wyssling, Herzog, Hess, Meyer, Wergin, and others. The cellulose component of the membrane is made up of cellulose particles (1.25 μ in diameter) whose relation to the other membrane components he compares to the relation of the cells in a honeycomb to the comb itself. This is an excellent analogy to be used in large numbers of cells where fibrils are not formed and is likewise descriptive of the appearance of the fibrillar wall of a cotton fiber when particles are pushed apart by the swollen cementing material (Fig. 9d). Wieler's techniques have included certain staining and swelling treatments not used by Farr and Eckerson and, from his description, it is clear that some of these are useful in bringing out more clearly finer structural details. In all cases in which the honeycomb structure was found, he obtained a positive cellulose reaction with $\text{H}_2\text{SO}_4 + \text{I}_2\text{KI}$ for the contents of the small cells (cellulose particles), while he found that the surrounding substance consisted of other chemical substance concerning the nature of which, he states, nothing can yet be said.

Finer structural details of cell membrane than have hitherto been observed are now being shown in studies made with the electron microscope. In the greater number of images there are shown extremely fine, clearly defined fibrils far below the limits of microscopic resolution. The plates which have been published by Ruska and Kretschmer,²¹³ Sears and Kregel,²³⁴ and Barnes and Burton¹⁹ are representative of the group, and the reproductions are characterized by a greater clearness than in many of the others. In addition to the fine fibrils there is shown globular material, apparently of a different composition, ranging in shape from spherical to ellipsoidal in both the swollen and unswollen states. From magnification and descriptions these appear to be approximately 1 μ in size, with the exception of a more or less linear group shown by Barnes and Burton, which are approximately half that size. The finely fibrillar material is designated as cellulose by most of the authors, although it is referred to as "skin substance" extracted from wood pulp by Sears and Kregel.²³⁴ The globular material has no such specific designation. In view of the heterogeneous chemical and physical nature of the cell membranes which form the subject matter for such studies, it is probable that careful separation and identification of all the separable constituents before examination will be helpful in utilizing this new technique to its fullest capacity. From the data thus far presented,

it is questionable whether, or to what extent, the images obtained with the electron microscope represent structures of cellulose as such.

Discussion

A review of the accumulated information concerning the formation and structure of plant-cell membranes reveals the fact that data concerning the microscopic structure of the mature membrane began to accumulate even before the time of recognition of the cell as the unit of structure in plant and animal tissues. Lyngbye reported the presence of "minutissime punctata" in the membrane of *Gastridium ovale*, now classified under the name of *Halicystis ovalis*. Valentin, using cells of different types and of smaller dimensions, was able to see something of the relationship of the protoplast of the cell to the cell membrane. Through his studies and those of many of his contemporaries it soon became evident that the cell membranes were increasing in thickness by the deposition of material from the protoplasm upon their inner surfaces. This observation led to the question of what kind of material is thus deposited from the protoplasm; Valentin, searching for an answer to this question, found granules which, in many types of cells, joined together end-to-end to form fibrils, and which were then moved from the protoplast into the developing cell wall. These earliest workers were not concerned with the chemical composition of these structural units. Their viewpoint was as that of an observer whose attention is held by the process of construction of a wall from bricks and mortar, without particular interest in the exact composition of the materials themselves. The brilliant researches of Prout, Payen, Fremy, and others furnished a basis for distinguishing between *proteins*, *carbohydrates*, and *fats* in the cell and served in turn to differentiate the carbohydrates into *sugars*, *starch*, and *cellulose*.

Confronted with the facts that sugar, starch, and cellulose are products of living protoplasm, the next problem in this field was to find *where*, in the living protoplast, these substances come into existence and, if possible, how they are used by the cell during its period of vital activity. In the course of these investigations it was found that sugar is usually in solution in the protoplast, and that cellulose and starch represent visible forms of carbohydrate in the cell. As early as 1837 von Mohl found that the granules of starch were formed in the *chloroplasts*, and the subsequent studies of Sachs, Schimper, Meyer, and others revealed the fact that the necessary conditions for starch formation exist only in these special morphological structures in living cells, *chloroplasts* and *leucoplasts*.

The starch granules themselves were found to develop by deposition of materials from the plastid plasma around small, starch-forming centers. This early linking of *starch* formation with a microscopically visible, morphological process has served to protect it, in some measure, from theoretical attacks upon its molecular structure, based entirely upon considerations of certain properties of mature starch grains. If one is free to assume that a substance "crystallizes" or "polymerizes" directly from the cytoplasmic substratum of the cell, laws which are believed to govern such crystallizations or polymerizations, as they take place in the test tube, can be theoretically applied. In connection with starch formation, this freedom has not been permitted, for the theorist has been confronted with facts of the visible aspects of its organized synthesis which can be adequately explained by no known laws of molecular behavior.

Cell membranes, until recently, have not had similar protection. Although nineteenth-century researches, which have been previously reviewed, furnished adequate evidence that microscopically visible granules formed in the protoplasm are used in the construction of plant-cell membranes, and that these units, along with other materials of protoplasmic origin, maintain their identity in the mature cell membranes, the cellulose nature of these protoplasmic granules was not known until they were identified microchemically by Farr and Eckerson in 1934. Even then it

was not known *where* they are formed in the living protoplast. While this lack of information existed, their method of origin was a matter for speculation. It was conceivable that they might crystallize or polymerize from the basic cytoplasm directly. Their existence in the form of visible particles and fibrils in the living protoplasm, however, excluded the possibility of membrane formation by deposition of molecular layers upon the inner surface of the cell membrane. The recent discovery of cellulose-forming plastids, in which the stages of development of cellulose particles are distinctly visible, now affords to cellulose the same degree of protection from theoretical consideration that has been afforded to starch. The gradual separation of cellulose-forming material from the plastid plasma, the gradual solidification of this material into rings of uniform thickness, the fragmentation of the rings into particles of remarkably uniform size, the active Brownian movement of these particles in the plastid plasma, the direct deposition of the entire plastid content in the cell membrane, as in *Halicystis*, and the intermediate stage of fibril formation preceding deposition, as in cotton, are processes even more elaborate and complex than the visible aspects of starch grain formation. And, as though Nature were not sufficiently satisfied with the complexity of successive ring formation and disintegration in the process of cellulose formation, we have found more recently, in the chloroplast of *Valonia*,* a different type of behavior (Fig. 14). Following the formation of a single closed cellulose ring (a), a cellulose fibril begins to form within the young plastid (b). Its various stages of development are somewhat obscured by the green plastid plasma with which it is surrounded (c, d), but if the plastid membrane is removed and the plasma partially washed away with distilled water, the original cellulose ring and the coiled cellulose fibril are more distinct. Two plastids thus prepared are shown in (e). After removal of the plastid membrane from mature or nearly mature chloroplasts, the fibrils quickly straighten and, with the usual manipulations involved in the dissections, tend to separate readily into cellulose particles (f). How frequently such fragmentation occurs in the living cell is not known. It would seem to be comparatively rare, however, from the examination of the inner surface of a fresh membrane. There the fibrils, uncoiling from the plastids, can be seen in the act of aligning themselves with previously deposited fibrils in the developing wall lamella (g, h). The precision with which this alignment takes place is evidenced both by the microscopic appearance and the x-ray diffraction pattern of the mature cell membrane (j). It is probable that this direct formation of the fibril within the plastid and its deposition, without disintegration, in the membrane, accounts for the high degree of crystallinity in the mature membrane, as shown by x-ray diffraction analysis. The organization of fibrils from separate particles, as in cotton fibers, can thus permit the incorporation of colloidal materials upon the surfaces of the particles, and less perfect alignment of the particles than is found in the fibril of *Valonia*, which, once formed in the plastid, apparently remains intact.

The formation of cellulose in the living cell has been found to take place, therefore, in a specialized cytoplasmic organ, a cellulose-forming chloroplast or colorless plastid. This formation has no visible aspects in common with the process of starch formation. As far as we know at present, the production of these two closely related carbohydrates always takes place in separate plastids, even though their formation goes on simultaneously in this connection. A true understanding of the structure of the mature cell membrane must take into account these developmental factors which permitted it to function, originally, as a part of a living organic unit. Bensley,²³ in commenting upon the dilemma of the application of the concept of molecular pattern to the problem of protoplasmic structure states,^{p. 390} "Protoplasm on the contrary respire, excretes, performs complicated chemical operations, uses or liberates energy

* A detailed report of cellulose membrane formation in *Valonia* is to be published in a forthcoming issue of the Contributions from Boyce Thompson Institute.

and reproduces its own substance in kind. This metabolism can be imitated in part *in vitro* . . . but in the cell is characterized by speed, orderliness, and rhythm not to be found in a random mixture of chemical substances in solution." The production of physically and chemically complex structures such as starch grains and cell membranes are clear evidence of this coordinated behavior.

As shown in Fig. 6 the new theory of the construction of cell membranes from "fringed micells" has had a gradual evolution from the original concept of Nägeli that cell membranes are composed of submicroscopic crystalline micellae surrounded by films of water. This concept of membrane structure, shown diagrammatically by Frey in Fig. 6a, is shown in greater detail by Seifriz (Fig. 6b), in order to incorporate knowledge of molecular structure contributed by x-ray diffraction analysis. The possibility of disorderly as well as orderly arrangement of the micells is brought out in the illustration according to Mark shown in Figure 6c. The configurations of both orderly and disorderly arrangements with respect to cell membranes are shown in Fig. 6d, after Frey. These conceptions of cell-membrane structure necessitate no consideration of chemical inhomogeneity in the membrane and only such physical inhomogeneity as can be explained upon the basis of variations in micellar arrangement. It will be remembered, however, that even Nägeli observed that the *micellae* were comparatively stable and that changes in them do not account for the plastic properties of swollen membranes. For this reason he postulated that they are separated by water films which could increase or decrease in thickness while, in the meantime, the *micellae* themselves did not swell. This stability of the crystalline phase of the membrane has continued to be in evidence as measurements with newer techniques have been developed. Successive treatments of the membranes with chemical reagents may reduce them to a fine white powder which still gives the x-ray diffraction pattern of native cellulose. Upon the basis of *visible* cellulose crystallites it is seen that the coating of protoplasmic material, acquired by the particles before deposition in the membrane lamellae, has been removed more or less completely by the chemical reagents and the cellulose particle itself has shown in many instances no evidence of reaction with them. The conception of *invisible* structure found a theoretical basis for the explanation of these regions of greater and less sensitivity in the membrane in the work of Carothers dealing with chain molecules of unequal length (Fig. 6e). Adapted to cell-membrane structures, these appear as the "fringed micells," as shown by Kratky (Figs. 6f, g) and find their final representation, in two dimensions, in both the organized and disorganized states as shown by Freund and Mark in Fig. 6h.

This conception of cell-membrane structure has abandoned the original idea of discrete *micellae* surrounded by water. It is now stated by Berkeley²⁴ that between the dense areas *amorphous cellulose* surrounds the *fringe molecules*. The properties of amorphous cellulose, its microchemical reactions, etc. are not described. Membrane structure and composition of this type presumes, however, a clean-cut separation of crystalline and amorphous cellulose from all other protoplasmic constituents in the process of formation of the membrane lamellae, a consideration not substantiated in the observations of cell membrane formation in *Valonia*, *Halicystis*, the cotton fiber, and many other types of cells. These assumptions of a fringed micellar membrane structure have been evolved from chemical and physical studies of mature membranes. Membrane formation from cellulose particles held together with colloidal protoplasmic materials has, as a background, the entire process of the formation of visible structural components from the time of the beginning of their synthesis in the cellulose-forming plastid of the living cell. It is of interest, therefore, to compare the similarity between the diagrammatic representation of the fringed micellar structure as shown in Fig. 6h and the photomicrograph of the structure of the cotton fiber as shown in Figs. 8c and 15a, b, c, d. From the physical viewpoint the difference seems to be largely in size of the structures concerned—the crystallites and the intercrystalline material in the one case being microscopically visible, and in the other microscopically invisible.

The microscopic problems involved in observing the formation of cellulose particles in a colorless plastid of a cotton fiber, in following these cellulose particles through their subsequent alignment to form fibrils and the fibril deposition on the inner surface of the cell membrane, are those which are encountered in any attempt

FIGURE 15. Top: Membrane of mature cotton fiber disintegrates into fibrils, in turn, into cellulose particles. B. to observe a colorless, more or less translucent object imbedded in a matrix of very similar refractive index. Microscopists of the last century who worked with fresh material, lights of low intensity, and "high-dry" lenses with adequate resolving power were better equipped for such observations than many modern laboratories in which microscopic equipment, including the illuminating units, has been designed for use with killed, heavily stained tissues. With regard to the observation of the

individual particles and their subsequent behavior in cell-membrane formation Farr^{58, p. 229} stated in 1937, "The degree of magnification needed to bring them into clear relief is near to one thousand diameters. Within the short focal distances involved, there is still a wide variation in the sharpness of focus of the different particles in any given field. Apparent differences in size often result from these variations in the sharpness and are not real. The approximate length of a single particle as it exists in the living cell is 1.5 microns. This measurement is believed to be very nearly correct since it is possible to check it with the average length per particle in chains of varying numbers of particles arranged end to end." "The length of the short axis is not so easily determined and may be verified only through comparison with the long axis, since, in the cotton fiber, the associated particles are always in single rows, end to end, and not side by side. The value which seems to be most nearly accurate for the length of the shorter axis is 1.1 microns. It must be pointed out that all measurements of a structure of this size and composition under the necessary optical conditions is difficult and is, at best, an approximation." Failure to see cellulose particles of this size at low magnifications is then to be expected.¹³² Their confusion with crystalline granules which appear in drying solutions of cuprammonium hydroxide, however, could not take place with an observer familiar with the refractive indices, solubilities, and other properties of cellulose particles.^{132, p. 324}

The refractive indices of cellulose particles taken from the living cytoplasm of the cotton fiber by the immersion method were found by Farr and Eckerson to be 1.565 lengthwise and 1.530 crosswise. Concerning these measurements Anderson and Kerr state:^{10, p. 53} "The refractive indices of native cellulose have been measured in various cell walls by a number of different workers."⁹ Frey-Wyssling determined the refractive indices of the cellulose in cotton fiber and found them to be $n_v = 1.596$ and $n_a = 1.534$. These values are in excellent agreement with those obtained by other investigators on other native celluloses. They are not in agreement with the values reported by Farr and Eckerson⁷ for ellipsoidal particles observed in the protoplasm of cotton hairs."

Results of other workers in refractive-index measurements of native cellulose are tabulated below for convenience in comparison with the values obtained by Frey-Wyssling and Farr and Eckerson: *

| Author | Material | n_v | n_a |
|-------------------|----------------------------|-------|-------|
| Schlotman | Cotton fibers (greenhouse) | 1.565 | |
| Preston | <i>Adamsonia digitata</i> | 1.564 | 1.531 |
| " | <i>Agave perfoliata</i> | 1.559 | 1.536 |
| " | <i>Yucca gloniosa</i> | 1.554 | 1.537 |
| " | Cotton fibers | 1.578 | 1.532 |
| Shaw | Water lily | 1.568 | 1.534 |
| Farr and Eckerson | Cotton fibers | 1.565 | 1.530 |
| Chamot and Mason | | 1.59 | 1.53 |
| Frey-Wyssling | | 1.596 | 1.534 |

These values show that the n_v index is almost identical for all authors. Comparisons of methods used and comparative states of material at the time of measurement show that n_v indices measured under similar conditions agree closely, e.g., Schlotman, Shaw, Farr and Eckerson. The high values for n_v , as shown by Frey-Wyssling and Chamot and Mason, can be interpreted as due to the fact that both authors made the measurements upon entire fibers in which the orientation of fibrils is not parallel either to the long axis of the single fibril or the long axis of the single cellulose particle. These and other questions concerning the existence of cellulose

* From a more detailed comparison of values and methods to be published later by Farr and Eckerson in the Contributions from Boyce Thompson Institute.

FIGURE 16. A, B. Dilute dispersion of cellulose xanthate shows cellulose particles in ordinary and oblique illumination (X 840). C. particles in the protoplasm of living cells and in cell membranes have been considered in other publications from our laboratory.^{59, 20}

Another group of papers describing the behavior of cotton-fiber membrane constituents in cuprammonium hydroxide and during xanthation^{59, 42, 239, 43} showed, by means of microscopic studies in ordinary and polarized light and in dark-field, microchemical determinations, optical rotations, x-ray diffraction analyses, and observations of electrokinetic and coagulation behavior, that in these two industrial processes the cellulose particles undergo no visible physical change, but that the intercrystalline continuous fiber phase is considerably altered by the reagents employed (Fig. 16). Farr, using the standard solution of cuprammonium hydroxide specified by the American Chemical Society, containing 30 ± 2 g of copper, 165 ± 2 g of ammonia, and sucrose in the proportion of 10 g per liter, found microscopically that the fiber is transformed, in this solution, into a swollen mass of cementing substance in which the cellulose particles are dispersed. All other results by the various techniques employed by Farr, Sisson, and Compton corroborated this general conclusion. In an attempt to trace the source of the viscosity-producing fraction or fractions of the cementing material Farr states:^{59, p. 89} "The one fraction of the cementing material of the cotton fiber which we had been able to separate and identify in sufficient quantities for such a study was the component which is extracted with 0.5 per cent ammonium oxalate. Upon the basis of uronic acid anhydride determinations according to the method of Dickson, Otterson, and Link this extract was identified as pectic material." ^{p. 91} "When 0.625 g of this powdered pectic substance was added to 100 cc of the A.C.S. standard solution of cuprammonium hydroxide, the viscosity of the cuprammonium solution was increased from 3 min, 43 sec, to 11 min, 24 sec. The addition of 1.25 g to 100 cc of the solution increased the viscosity to 26 min, 10 sec. Table IV shows the result of adding increasingly larger amounts of pectic material to the point when over ten hours were required for the mixture to flow through the viscosity tube. Any quantity of this pectic extract over 5 g per 100 cc produced a gel so stiff that it would not flow." ^{p. 93} "The mixtures of pectic material and cuprammonium hydroxide were distinguished by their sparkling clarity, and their greatly reduced tendency to 'separate' as compared with the mixtures containing either raw cotton or both extracted pectic material and separated cellulose particles."

It was shown in Farr's data that if 1.87 grams of this powdered material were added to 100 cc of cuprammonium hydroxide, a viscosity approximately comparable to that of 0.25 g of cotton linters in the same quantity of cuprammonium hydroxide was obtained. In discussing these facts Farr states:^{59, p. 91} "It must be emphasized, therefore, that in studying directly the viscosity-producing power of this extracted pectic substance we were using only one of the possible viscosity-producing components of the cementing material and that its original viscosity-producing power had been markedly reduced by extraction and repeated purification."

In commenting upon his observation that quantitative examination of variously treated plant fibers dispersed in cuprammonium solutions, using a slit ultramicroscope, reveals the presence of approximately the theoretical number of cellulose particles ($1.1 \times 1.5\mu$), Compton^{42, pp. 60-67} states: "The two general methods employed for the gradual chemical disintegration of plant fibers are: first, the action of dilute acids, and second, the action of mild oxidizing agents. The disintegration of plant fibers in this manner is accompanied by a lowering of the cuprammonium viscosity (Table I) which has been previously interpreted as being due to a decrease in the chain length of the cellulose molecules. Based on the dual structure of plant fibers, however, a new interpretation is now placed on this behavior. Since the crystalline phase, or cellulose particles, remains largely intact by these treatments, it follows that the intercrystalline "cementing" material is the fiber phase most easily extracted or modified. The conclusion may also be drawn that this unstable, reactive phase of native plant fibers is largely responsible for the high viscosity when dis-

persed in cuprammonium solution. This interpretation is somewhat similar to that of Joyner,¹⁶ who postulated the existence of a cellulose A with high and a cellulose B with low viscosity in native plant fibers."

Sisson, in commenting upon his observations upon the dispersion, electrokinetic and coagulation behavior of cotton fibers in cuprammonium hydroxide solution, states: ^{239, p. 121} "The most common visible unit of dispersion appeared to be small uniform-sized particles of cellulose. After complete fiber disintegration the apparent number and nature of the particles did not change even after storage of the solution in an ice box for two weeks." ^{p. 125} "In the fiber, the indications are that the cementing material⁴ may form a true lyophilic colloid which may swell indefinitely with the dispersion medium. Cellulose particles on the other hand would appear to be lyophilic to the extent that cuprammonium solution enters into the cellulose particle to form a swelling compound, and lyophobic to the extent that during his process the particle itself is not measurably altered in size and shape."

These data indicated that the cuprammonium viscosity of cellulosic materials was not dependent upon any one of the many fiber components alone, but rather was dependent upon the colloidal system (cellulose particles, intercrystalline material) present in native fibers. In commenting upon the observations which led to the conclusions, Farr states: ^{59, p. 91} "These miscellaneous examples are cited in order to emphasize further the need for more knowledge of the viscosity-producing power of the non-cellulosic cell membrane constituents under a wide range of experimental conditions."

Further research in these fields should again lead to improvements in the techniques of separating, identifying, and maintaining the colloidal properties of the membrane components from many types of plant cell membranes and to a better understanding of the parts played by these components in the viscous states of cell membranes in many types of reagents. It could be expected that many of the anomalies of the viscosities of colloidal solutions would be clarified by a concerted attack with microscopic, chemical, x-ray diffraction, electron-diffraction, electrokinetic, and other techniques whose values have been established in these fields of colloid-chemical research. The parts played by the dispersed cellulose particles, the colloidal nature of the cuprammonium solution itself, and the swollen cementing material might thus be found to fall within known fields of colloidal behavior.

This experimental work with one extracted fraction of the non-cellulosic fiber material has been taken by Howells,¹³⁴ Heuser and Green,¹³⁰ and Hock and Harris¹³² to mean that we * believe that the viscosity produced by cell membranes of cotton fibers in cuprammonium hydroxide is due *entirely* to the pectic material in the membrane. Their attempts to find dispersed particles of cellulose in cuprammonium hydroxide and to produce viscosities in cuprammonium hydroxide with any extracted membrane material other than cellulose have failed. These points will be settled only by further experimentation by other workers. One of the important preliminary studies for such an experiment is that of learning to recognize the cellulose particle in the living protoplasm of the cotton fiber and in disintegrated mature-cell membranes. While this technique is not exactly simple to employ, it is much less difficult than the identification of the crystallites in the midst of the swollen, blue matrix of cementing material in cuprammonium hydroxide solution.

Wieler's²⁶⁷ recent comments concerning swelling reactions should also prove to be helpful in this connection. In describing the phenomena encountered in the study of swollen cotton-fiber membranes, he emphasizes the confusion produced by the mixture of fibrillar materials in the microscopic field. It was only after more careful manipulation of the reagents used in producing the swollen mass that he was able to trace the source of the finely fibrillar material to the inter-particle substance in the membrane and to distinguish its microchemical reactions from that of the cellu-

* Farr and coworkers.

lose reaction of the particles. These microchemical distinctions are difficult to make but important to master, if a true understanding of the cell membrane is to be obtained. Observations of the structure of plant-cell membranes which have accumulated for more than a century have dealt, in many instances, with cells in which cellulose fibrils are conspicuous structural units. Descriptions of cell walls in which cellulose fibrils are not present, such as *Halicystis*, are not frequently found, although the earliest reports of the fine structure of cell membranes were upon cells of this type. The first reports of fibrils in membranes of various plant cells were based upon the fact that the microscopists *saw* them in the fresh, untreated tissues, commented upon their uniformity in diameter, and even followed their formation from the alignment of granules in single rows in the protoplasm of living cells.^{262, 226, 198} With such techniques they were likewise able to distinguish membranes in which fibrils do not occur.¹⁶⁰ Wieler's recent emphasis upon the "honey-comb" structure of membranes will undoubtedly serve to broaden the current conceptions of plant-cell membrane structure in general. Likewise, the detailed observations of the finely fibrillar nature of the swollen intercrystalline membrane substance may help to throw some light upon the reports of the appearance of *anastomosing fibrils* grading down to and beyond the limits of microscopic visibility. In consideration of the fibrillar structure of cell membranes it is important that the cellulose fibrils, which can be seen to form within the plastids of living cells or from uniform-sized granules produced in such plastids, be distinguished as such from those finely fibrillar formations which make their appearance in advanced stages of membrane swelling. Little is known of the chemical composition of these fibrillar materials. Baier and Wilson¹⁸ offer a possible clue in their descriptions of the formation of fibrous pectate pulps. Based upon these findings and observations of the high mineral content of the intercrystalline fiber material,²¹⁰ Marquette¹⁶⁵ has recently suggested that the finely fibrillar images of cotton and wood fibers as shown by the electron microscope may represent "ash-patterns" of the intercrystalline material, when high temperatures are involved.

SUMMARY

1. One of the earliest known descriptions of the cellular structure of plant tissues is to be found in Hooke's "Micrographia," published in 1665. An illustration of a cross-section of cork tissue accompanies the description.

2. During the eighteenth century improvements in the construction of microscopes and the development of organic-chemical techniques laid the foundation for the important discoveries of the nineteenth century in the structure and composition of plants and animals.

3. The nature of the process by which plants produce complex organic substances from simple inorganic materials was a clearly defined, biological problem at the beginning of the nineteenth century. The dependence of both the plant and animal kingdoms upon these original syntheses was recognized but not understood.

4. The identification of the cell as the unit of both plant and animal structure in 1838 shifted the search for the seat of this synthesis from the plant as a whole to the single cells of its tissues.

5. The *chloroplast* in the protoplasm of the plant cell, not found in animal cells, was found to be the structure in which carbon dioxide and water are united to form sugar. This process, named "photosynthesis" in 1898, is the first step in the production of all simple and complex organic materials.

6. The classification of organic substances into *carbohydrates*, *proteins*, and *fats* by Prout made possible the identification of these substances in the plant cell before 1850 and marked the beginning of the science of *microchemistry*—the microscopic observation of chemical reactions.

7. The further classification of carbohydrates into sugar, starch, and cellulose

permitted a more detailed study of these substances in living cells. *Sugar* and *starch* were found to be produced in chloroplasts and colorless plastids. In the earlier microchemical work *cellulose* was identified only in plant-cell membranes.

8. Observations of the fine structure of plant-cell membranes were made as early as 1819 by Lyngbye who reported "minutissime punctata" in the membrane of *Halicystis*. A drawing of this membrane accompanies his description and shows the arrangement of granules in the membrane similar to the arrangement which appears in a modern photomicrograph of the same membrane.

9. Fibrillar structures were observed in fresh plant-cell membranes before 1840, and their origin in the protoplasm from the alignment of minute particles in single rows was described.

10. These early observations showed that the plant-cell membrane increases in thickness by the deposition of visible granular or fibrillar structures from the protoplasm on the inner surface of the original limiting membrane of the cell.

11. Nägeli postulated his *micellar hypothesis* in 1858 to explain all the physical aspects of vegetative and reproductive phenomena upon the basis of submicroscopic unit structures—micellae [The micellae concerned in hereditary phenomena were specifically designated as "ids"]. All visible structures in the plant-cell membrane smaller than the fibril and all of its microchemical differentiations were ignored in the formulation of this micellar hypothesis. The membrane was described as consisting of submicroscopic crystalline micellae surrounded by films of water which could increase and decrease in thickness during alternate swelling and desiccation. Upon the basis of observations in polarized light, the micellae were found to be unchanged during the process of swelling.

12. These observations were at variance with the contemporary reports of physical and chemical heterogeneity of the plant-cell membrane materials made by Payen, Fremy, and others.

13. Strasburger suggested the name *microsomes* for the granular structures which appear in the protoplasm and are used up in the formation of the cell membrane. He identified them microchemically as protein granules.

14. Wiesner suggested the name *dermatosomes* for these structures and stated that although they are evidently protein while free in the protoplasm, they change, in some mysterious manner, into cellulose after they are deposited in the cell wall.

15. Important advances in the knowledge of the orientation of crystalline cellulose in plant-cell membranes were made by Ambrohn between 1890 and 1925 through careful measurements in polarized light.

16. The crystalline nature of the cellulose component of plant-cell membranes was confirmed by x-ray diffraction analyses in 1913, and Ambrohn's conclusions concerning the orientation in various types of cell membranes were rapidly corroborated.

17. By means of x-ray diffraction technique the first approximate measurements of the unit cell of cellulose were made by Sponsler in 1926.

18. X-ray diffraction analyses and measurements of viscosities of gelatinized cell membranes have been used in the development of a new theory based originally upon the conception of chemical and physical homogeneity of the cell membrane, but revised recently to represent chemical and physical inhomogeneity. It is now designated as the *fringed micellar hypothesis*. The gradual evolution of this hypothesis from the micellar hypothesis of Nägeli is shown in a series of diagrammatic sketches from the work of various authors.

19. The identification of crystalline cellulose in living protoplasm of cells from all parts of the plant kingdom was made by Farr and Eckerson in 1934. The unit crystallites were named *cellulose particles* and their identity with Lyngbye's "minutissime punctata," Valentin's *granules*, Strasburger's *microsomes*, and Wiesner's *dermatosomes* was established upon the basis of their location and general behavior

in the protoplasm during the formation of new lamellae and their presence in the mature membrane of the plant cell.

20. The presence of intercrystalline material in the cell membrane was shown by Farr, Eckerson, Sisson, and Compton to account for many of the physical and chemical properties of the cell membrane. Its chemical complexity and the possibility that it contains many protoplasmic constituents of the cell from which it is formed were early recognized.

21. The existence of cellulose crystallites of slightly smaller dimensions has been shown by Lüdtkke, Hess, Wergin, Lieser, and others. The existence of cellulose particles of approximately the same size as those described by Farr and Eckerson has been shown by de Mosenthal, A. J. Bailey, Roberts and Haring, and Wieler.

22. The existence of visible cellulose crystallites in the protoplasm of living cells and in cell membranes has been denied by I. W. Bailey, Anderson and Kerr, Harris and his associates, and Berkeley. The physical and chemical behavior of cell membrane constituents in cuprammonium hydroxide as described by Farr, Compton, and Sisson has been denied by Harris and associates, Heuser and Green, and Howells.

23. The two polysaccharides, *starch* and *cellulose*, are formed simultaneously in separate plastids in the same cell. In certain cells the entire plastid plasma, including the chlorophyll, is deposited in the formation of a new lamella of the cell membrane.

24. The organization of the membrane lamella from cellulose crystallites and intercrystalline material of plastid and cytoplasmic origin takes place in the outer regions of the protoplast. Wieler has recently emphasized the importance of this function of the living protoplast which apparently has been overlooked by Frey-Wyssling, Wergin, Lüdtkke, and others.

25. Current explanations of the physical and chemical properties of plant-cell membranes are made, in general, upon the basis of either submicroscopic "fringed micells," postulating continuous cellulose chain structure interspersed with more or less homogeneous, amorphous material, or upon the basis of microscopically visible cellulose particles or fibrils and a chemically heterogeneous cementing material which is composed of many of the protoplasmic constituents of the cell in which the membrane materials were formed.

26. The early identification of starch grains in chloroplasts linked their formation inextricably with biological processes of unknown physical and chemical nature and has served to protect them, in some measure, from attempts to explain their method of formation and chemical and physical properties upon a simple molecular basis.

27. The recent discovery of cellulose-forming plastids, in which the stages of development of cellulose particles are distinctly visible, now affords to cellulose a similar footing in observable phenomena, providing a brake to theoretical overspeculation.

28. The chemical and physical heterogeneity of plant-cell membranes indicates the necessity for improvements in the techniques of separation and identification of their intimately associated constituents, and in the measurement of the unknown forces which are involved in the synthesis and distribution of membrane-forming substances in the living plant cell.

Recent Advances in Starch Chemistry

R. M. HIXON AND R. E. RUNDLE

Department of Chemistry, Iowa State College, Ames, Iowa

Basic to the study of starch is a knowledge of the nature and degree of its heterogeneity. That starch is not homogeneous was claimed as early as 1819 by de Sausure on the basis of differences in solubility of component parts of the granule. The conflicting systems of nomenclature which resulted from the numerous subsequent attempts at fractionation are reported in the more extensive reviews by Alsberg,¹ Hanes,² Radley,³ Samec,⁴ and Walton.⁵ The difficulties were due largely to lack of methods for characterizing the component fractions. There were no criteria for complete fractionation and no methods of interpreting the results, even of excellent fractionations such as that of Baldwin.⁶ The use of unfractionated or partially fractionated starch in the numerous studies by methylation techniques confused the issue until the heterogeneous character of these materials was clearly recognized.

Recently K. Meyer⁷ has given new significance to work on the fractionation of starch by hot-water extraction and retrogradation. He has given a clear differentiation of the components on a structural basis and shown that starch consists of branched and unbranched molecules. The branched component has a much greater molecular weight than the unbranched, and constitutes the major portion of the starch. Excellent summaries of these studies have been published by K. Meyer^{8,9} in the last two years. He has used the older terms "amylose" and "amylopectin" to designate the two components in starch. Retention of the terms will retain some of the confusion associated with their use in the older literature. Criticism might also be raised to retention of "pectin" in the nomenclature. Nevertheless, the fact that definite structural interpretations have now been given to the terms makes it seem

advisable to continue that usage rather than to introduce new terminology. Accordingly, in this summary the term "amylose" will be used for the unbranched component in starch, and "amylopectin" for the branched component.

The concept of branched molecules is not new. It was suggested as possible for xylan¹⁰ in 1934 and for glycogen¹¹ in 1937 to explain the presence of monomethyl xylose and dimethyl glucose after hydrolysis of the methylated polysaccharides. The laminated formulation

was also used in the latter publication to illustrate such a branched structure, the arrowhead representing the reducing end of a chain of glucoses linked to unspecified positions in the other chains. At the time, however, there was still reservation as to complete methylation of the polysaccharide. There was also reservation as to whether the linkage between chains was due to an ordinary covalent bond or to a "coordinated" or "hydroxyl" bond.

The present evidence for the structure of starch has also come from a number of other sources. Staudinger and Eilers¹² furnished experimental evidence that the large molecules of starch exist as definite molecular entities rather than indefinite micelles composed of many small molecules held together by secondary valences. In this work, partially degraded starch was acetylated; the acetylated starch was in part regenerated and in part converted to methylated starch. Measurements of molecular size in several solvents gave comparable values for the original starch, and the acetylated, the regenerated, and the methylated starch. Following this work, Staudinger and Husemann¹³ pointed out the value of a branched structure as an explanation for the discrepancies between the physical measurements and end-group assay in determining molecular size. In 1940, Freudenberg and Boppel¹⁴ identified the dimethyl glucose obtained in the hydrolysis of methylated starch as 2, 3-dimethyl glucose, and concluded that α -1,6-glucosidic linkages must be present in addition to the customary α -1,4-glucosidic linkages.

The Amylose and Amylopectin Components of Starch

The differentiation between branched and unbranched molecules in starch has been confirmed by physical methods.¹⁵ It has been shown that the amylose component (unbranched molecules) is oriented easily by flow while the amylopectin component (branched molecules) is oriented with difficulty, if at all. While viscosity results have not been published, sufficient data are at hand to state that these studies confirm the linear and non-linear character of the two components.⁶² The difference is also shown in a striking manner by the filming properties of the two fractions and by the characters of their acetyl derivatives; the fibrous, cotton-like character of amylose acetate as compared to the very brittle quality of amylopectin acetate is apparent even to the non-technical observer.

The molecular species responsible for the heterogeneity of starch may vary in size and in degree of branching. Several properties of starch and starch fractions indicate that, so far as branching is concerned, only two fractions are present. The amylose component is adsorbed preferentially on cellulose;¹⁶ it is precipitated in crystalline form by Schoch's butanol procedure;¹⁷ it forms a complex with iodine in water solutions which is quite different from the complex formed by amylopectin.¹⁸

The reaction with iodine has been made the basis of a quantitative determination of the amylose component. The iodine activity is measured potentiometrically.¹⁸ When iodine is added to an amylopectin solution, the iodine activity rises rapidly.

Upon adding iodine to an amylose solution, the iodine activity of the solution remains constant as long as complex formation takes place, and then rises with additional iodine as it does for water alone. Potentiometric titration curves of this type are shown in Figs. 1 and 2 for various starches, as well as for purified amyloses and amylopectins. If the quantity of iodine bound by Kerr's crystalline amylose³³ is taken as a standard, it is possible to estimate the amylose content of the different starches. The variation is considerable, as shown in Fig. 1 and summarized in Table 1:

Table 1. Amylose Contents of Starches Determined by Iodine Titration*

| Starch | Amylose (%) | Starch | Amylose (%) |
|--------------|-------------|-----------|-------------|
| Waxy rice | 0 | Corn | 21* |
| Waxy sorghum | 0 | Potato | 22 |
| Waxy corn | 0 | Popcorn | 23 |
| Waxy barley | 0 | Wheat | 24 |
| Tapioca | 17 | Sago | 27 |
| Rice | 17 | Lily bulb | 34 |
| Banana | 20.5 | | |

Upon examining any of the above-mentioned properties of starch, no evidence is found for components of intermediate properties, and it appears that none are present. It has been pointed out that amylopectin molecules must be quite branched in all portions of the molecule, since a long unbranched portion should act like an amylose molecule, and should be found in the amylopectin fraction by iodine titration.

It can be concluded, too, that amylose does not consist of long straight chains linked together with branched points. It has been demonstrated, at least for Meyer's amylose,¹⁹ that reducing and non-reducing end-group determinations lead to about the same molecular weight, and that physical determinations of the molecular weight are in substantial agreement with end-group determinations. This could be true only if the amylose were unbranched. Its behavior with β -amylase tends to confirm this point (*vide infra*). Amylose is completely, or essentially completely, converted to maltose by β -amylase, whereas amylopectin is not. The interpretation offered is that the enzyme starts at the non-reducing end of a chain, and continues to split off maltose units until it meets a branch-point, when it is stopped. If this interpretation is accepted, amylose cannot consist of long straight chains connected by branched points, since then a single branch point would suffice to protect a long-chain molecule from enzyme action.

If, then, it is agreed that starch consists of two components, one unbranched and one branched, the heterogeneity of each component can be examined. The above evidence will be taken to indicate that there is essentially no branching in amylose. Amylose can thus be heterogeneous only with respect to molecular size.

The amyloses from different starch sources are not identical in their behavior with iodine; for example, the iodine activity necessary for complex formation is distinctly different (Fig. 2). In general it has been found that the lower the iodine activity required for complex formation, the longer the starch chain. The results of the iodine titration indicate that the heterogeneity of chain lengths within a given amylose is fairly small, or at least less than that between amyloses from different sources.¹⁸ It is not to be inferred, however, that the amylose from any starch source is truly homogeneous as to chain length.

The differences indicated by the iodine titration for the chain lengths of the amyloses are supported by viscosity measurements.⁶² The results have not been previously published and are shown graphically in Fig. 3. No effort has been made

* Recently Dr. T. J. Schoch found that the removal of free fatty acid from cornstarch increased the value to about 28%. Similar increases can be expected for those starches which contain free fatty acid.

FIGURE 1. Titration Curves of Some Whole Starches.
(100 ml. of 0.04% solution)

to calculate the relative molecular weights, but for comparative purposes it may be stated that the particular amyloextrin fraction shown contained about 60 glucose units (calculated from reducing value measurements). The results indicate that molecular weights of the amyloses from various sources will exceed the range of 10,000-50,000 indicated by Meyer.⁸ The discrepancy is probably due to the fact that his extraction procedure gave only the shorter molecules from corn amylose, which is the smallest of all the amyloses.

The amylopectins could be even more heterogeneous than the amylose components, since they could vary in degree of branching as well as in molecular size. From the iodine titration curves, it can be concluded that the branches of the amylopectins are shorter than any of the amylose chains, since a long unbranched portion of an amylopectin molecule should titrate like amylose. Further, it will be noted that the titration curve for glycogen (Fig. 2) falls at a higher potential than for any of the starches. In this case, short branches have been indicated from methylation data,

since there is one end-group for every 12-18 glucose units. Where data are available for comparison, it seems true that the most highly branched amylopectins have the least affinity for iodine. On this basis it would be concluded (Fig. 2) that the branches of waxy starch molecules (no amylose component) are shorter than those of the amylopectins of the common starches.

FIGURE 3. Relationship between the Staudinger function, η_{sp}/C , and η_{sp} for some amyloses. The curves are numbered as follows: 1, amylopectin fraction; 2, synthetic starch; 3, corn amylose by Meyer's method; 4, mixture of 62.5% crystalline amylose and 37.5% amylopectin fraction; 5, corn "crystalline amylose" by Kerr's method; 6, corn butanol precipitate; 7, lily butanol precipitate; 8, tapioca butanol precipitate; and 9, potato butanol precipitate. The solid circles are for synthetic starch, curve 2.

While the evidence for the amylopectin component is not as complete as that for amylose, all available data indicate that branching is controlled with considerable precision by the enzyme system during synthesis of starch or glycogen. On the basis of degradation with β -amylase, Meyer²⁰ has come to a similar conclusion and has attempted to work out a pattern of branching in certain amylopectins.

Molecularly Dispersed Starch

Many of the important recent advances in starch chemistry have come about through the use of molecularly dispersed starch. The apologetic way in which many chemists still speak of starch solutions resulted from an earlier and erroneous

interpretation of methylation results. The case for molecularly dispersed starch will therefore be presented here.

Physical measurements²¹ gave molecular weights of a far different magnitude than the repeating units of approximately 25-30 glucoses found by end-group assay. The assumption had been drawn that starch in solution consisted of aggregates or micelles of many smaller molecules held together by secondary valence forces, although such a conclusion was carefully avoided by some workers.^{10, 11} When the importance of the hydrogen bond to chemistry was demonstrated, it was realized that in carbohydrates the situation was ideal for hydrogen-bond formation, and this type of secondary valence force was assumed to be responsible for the difference between chemical and physical molecular weights. As has been pointed out,¹³ branching of starch chains is a far better explanation.

There is good evidence that starch can be molecularly dispersed under careful conditions in water. It no longer seems questionable that this is essentially the case with such solvents as ethylene diamine, hydrazine hydrate, and chloral hydrate. Formic acid has also been suggested as a solvent for starch.²² In this case esterification takes place, the final analysis approximating one formyl group per glucose unit in the starch.²³

The viscosity and osmotic pressure of Meyer's⁹ amylose in several solvents has been shown to correspond to a molecule of about 200 glucose units. This figure is in agreement with the amount of tetramethyl glucose produced by methylation, and the amount of silver ion required to oxidize the aldehyde group on the other end of the molecule.

It would, however, be absurd to minimize the importance of secondary forces, particularly hydrogen bonding, on the properties of starch.²⁴ For example, in the well-known process of retrogradation, parts of the starch molecules in solution tend to arrange themselves into crystallites of definite structure, no doubt through the agency of hydrogen bonds. The large aggregates thus formed are insoluble. It is significant that retrograded starch produces the same type of x-ray diffraction pattern as does the original granule.

Starch molecularly dispersed in water is not stable at pH ranges below 7.0, except in very dilute solutions. However, the process of retrogradation is slow, and starch dispersed in alkali or by heat remains molecularly dispersed long enough for study, even in water solution. Such solutions are analogous to supersaturated solutions and, as they are unstable, care must be taken in carrying out and interpreting such reactions as enzyme digestibility, where molecularly dispersed starch solutions are necessary for quantitative results. That the degree of association of starch in solution can be made negligible during the course of such reactions, even in water solution, is clearly indicated by the work of Meyer on the β -amylase digestion of starch and its components (*vide infra*).

Crystalline Nature of Starch Granules and Retrograded Starch

In discussing the crystalline nature of starch, it should be emphasized that the term "crystalline" is used with certain limitations. The fact that an x-ray diffraction pattern is obtained is proof that molecular orientation is present. Even in the starch granule it is presumed that definite orientation of the molecules exists only in certain regions; such crystalline regions are termed "crystallites." This is similar to the situation existing in cellulose. Since these crystalline regions are probably small, it is possible for any single molecule to exist partly inside and partly outside of such crystalline regions; a long amylose chain, or different branches of an amylopectin molecule, might even be included within several such regions. Between crystalline regions, the orientation of the molecules is not complete; such non-oriented molecules would constitute amorphous regions in the granule. The crystallites are doubtless tied together by a network of this amorphous material.

It would appear that the branches of the amylopectin molecules are partly included in the crystallites, while the actual points of branching must remain in the amorphous condition. This follows from the observations that waxy starch granules (no unbranched component) are crystalline and that their x-ray diffraction pattern is like that of retrograded amylose.

Results of X-ray Diffraction. X-ray diffraction has not as yet contributed as much to the knowledge of the structure of starch as it has to the structure of cellulose, due in large measure to the fact that only powder diffraction patterns have been obtained from starch. Katz^{25, 26} was able to show, however, that granular starches produce two main types of patterns, the "A" patterns of the cereal starches and the "B" patterns of the tuber starches, with a few showing patterns intermediate in character. He also showed that low temperature caused starches of all sources to retrograde, producing diffraction patterns of the "B" or tuber type, while "A" or cereal type patterns are produced by starch retrograded at temperatures above 50° C.

Bear and French²⁷ were able to index both "A" and "B" diffraction patterns and to determine the unit cell of the starch structure. Their success was based on two new factors: First, they improved the quality of the diffraction patterns by recognizing starch as a hydrated substance and keeping it thoroughly wet during diffraction. Secondly, they demonstrated through a temperature series of diffraction patterns, that there is a continuous change from the "A" to the "B" modification. All intermediate patterns were obtained by varying the temperature of retrogradation. This led to a helpful correlation between the indices of the two crystalline modifications.

Bear and French report that both "A" and "B" modifications probably have triclinic structures of space group C_1^1 , although within their limits of error the "B" modification is orthogonal. The dimensions of the two units are given in Table 2.

Table 2. Dimensions of Starch Unit Cell*

| | a_0 | b_0 | c_0 | α_0 | β_0 | γ_0 | Vol. (\AA^3) |
|------------------------|-------|-------|-------|------------|-----------|------------|-------------------------|
| "A" Modification, ave. | 15.4 | 8.87 | 6.18 | 87.0 | 86.9 | 92.8 | 843 |
| "B" Modification, ave. | 16.1 | 9.11 | 6.34 | 90.0 | 90.0 | 90.0 | 930 |

The volume of the "B" unit is larger than that of the "A." This is in accord with the observation that the "B" modification is the more highly hydrated. Four glucose units are calculated to occupy a unit cell for both modifications. This size unit would require that the starch chains be essentially extended. For granular and retrograded starch it would rule out the helical chains suggested by Hanes² and Freudenberg²⁸ (see below).

Results of Optical Studies. Frey-Wyssling²⁹ has made a study of the optical properties of starch granules, and has interpreted her results in terms of structure. Starch granules are spherocrystals with the long axes of the starch molecules oriented radially with respect to the granule. The granules are quite birefringent; the dark cross with its center at the hilum is a well-known characteristic of all granules. Frey-Wyssling has found the spherocrystals to be optically positive; that is, light with its electric vector radial to the granule is retarded more than light with its electric vector normal to the radius of the granule. It is quite possible that a helical chain would have its greatest polarizability normal to the helix axis, while from Silberstein's theory (see note on p. 677) the polarizability of an extended starch chain could doubtless be along the chain. If these polarizabilities are accepted, the observed sign of birefringence would require extended starch chains.

* Recent film and fiber diffraction diagrams prepared from amylose in "B" modification indicate cell dimensions are $a_0 = 16.0$, $b_0 = 10.6$, $c_0 = 9.2$ Å; 10.6 is the fiber spacing. The gross aspects of the crystalline structure are discussed in an article to appear in J. Am. Chem. Soc. (1943).

in agreement with results from x-ray diffraction. "A" and "B" type granules are identical in these qualitative aspects.

The Helical Configuration of Starch and the Starch-Iodine Complex

Hanes² has noted in certain reactions with enzymes, notably with the enzyme produced by *B. macerans* where six-membered cycloamyloses are formed, that glucose residues six apart down the chain appear to be quite close to each other. He proposed, therefore, a helical starch structure with six glucose residues per turn in the helix. He also found that dextrans of more than six glucose residues intensify the color of iodine, while those below this figure do not. This was interpreted to mean that a full turn in the helix is necessary for the formation of the starch-iodine complex.

Freudenberg²⁸ built models of helical starch chains, and assuming a boat-shaped glucose ring, found that such helices should have the hydroxyls directed outward, leaving a hydrocarbon lining to the center of the helix. On this basis he would explain the blue color of the starch-iodine complex by placing iodine in the center of the helix, in an essentially hydrocarbon medium where iodine is known to give a blue color, rather than the red color which it produces in water or other polar solvents.

Neither Hanes nor Freudenberg has offered further evidence for their proposed configuration of the starch chain and the iodine complex. Recently evidence has been offered which leaves little doubt that the essential points of their proposals are correct when applied to starch in certain modifications, although it is clear that granular and retrograded starch do not possess a helical configuration. Since this confirmatory evidence has not been reviewed elsewhere, a rather complete treatment will be given here.

Katz³¹ found that if starch was gelatinized and then precipitated by alcohol rather than by retrogradation, the precipitated material gave a different x-ray diffraction pattern, corresponding to a new crystalline modification of starch. He named it the "V" modification, from "Verkleisterung"—gelatinized starch. This is a misnomer since it is produced by crystallization, the gelatinized starch having no crystalline structure.

In an article by Bear,³² attention was called to the fact that the "V" pattern bears some resemblance to the x-ray diffraction pattern given by the starch-iodine complex. He suggested that these patterns might result from helical structures such as those proposed by Hanes and by Freudenberg.

Schoch¹⁷ has fractionated starch by means of butanol. The "amylose" fraction precipitated by the butanol has the form of small rosettes, very birefringent and definitely crystalline in nature. These rosettes, when dried, produce a "V" type diffraction pattern of far better quality than any heretofore obtainable.

Kerr and Severson³³ have applied Schoch's butanol precipitation to the components of starch extractable by hot water (straight-chain molecules of shorter chain length). The resulting precipitate, which they named "crystalline amylose," appears indeed to consist of very minute single amylose crystals. These too produce an excellent "V" pattern upon drying, and one closely allied to it when still wet with butanol and water.

Final demonstration that the "V" configuration of starch and the configuration of the starch-iodine complex are related is provided by the treatment of "V" starch with iodine vapor.³⁴ Any starch, wet or dry, showing a good "V" diffraction pattern will absorb iodine vapor rapidly and in quantity, whereas dry granular or retrograded starch cannot be induced to absorb iodine vapor to any appreciable extent even under the most vigorous treatment. The ability to absorb iodine appears to be related to the quality of the "V" diffraction pattern the starch is capable of producing; Schoch's and Kerr's material are particularly good iodine absorbers. This,

incidentally, refutes all claims that water and/or iodide ion are necessary for starch-iodine complex formation. Whatever part they play under other circumstances must be related to their effect in aiding the starch chains to assume the "V" configuration.

The complexes formed from Schoch's and Kerr's butanol precipitates by treatment with iodine vapors give diffraction patterns of extraordinary quality. The resemblance between the diffraction pattern of the dry "V" material and the dry iodine complex is very pronounced. Rundle and French³⁴ find that the reflections from the iodine complex correspond to those from a two-dimensional hexagonal lattice, while those of the "V" pattern are more complex, probably corresponding to a three-dimensional hexagonal lattice or a pseudo-hexagonal lattice. The two-dimensional hexagonal lattice of the starch-iodine complex strongly suggests the closest packing of cylinders. This might be expected for the closest packing of helices. The two-dimensional character probably arises from random distances between the iodine molecules within the helix.

FIGURE 4. Diagram of the helical starch-iodine complex (drawn approximately to scale).

A graphical presentation of the helical starch-iodine complex is shown in Fig. 4. On the basis of this structure dichroism of flow of the starch-iodine complex in solution was predicted and found.¹⁵ This, with other optical properties, has provided one of the best checks on structure.

It is well known that iodine crystals are pleochroic. F. H. Spedding³⁵ has shown that the pleochroism can be explained if light with its electric vector parallel to the long axis of the iodine molecule is strongly absorbed, and light with its electric vector normal to the axis of the iodine molecule scarcely at all. In accordance with these facts, a helix lined with iodine molecules parallel to its axis should strongly absorb light with its electric vector parallel to the long axis of the helix, but should absorb very little light with its electric vector normal to the helix. Starch helices should be oriented by a velocity gradient such as that produced by concentric cylinder apparatus for observing birefringence of flow, and the oriented helices lined with iodine should show dichroism of flow; light with its electric vector parallel to the flow lines should be more strongly absorbed than light with its electric vector normal to the flow lines. This was experimentally observed by Rundle and Baldwin.¹⁵

A starch-iodine complex consisting of extended, essentially linear starch chains with the long axes of the associated iodine molecules parallel to the chain would also show dichroism of flow of the type observed. This model for the complex is eliminated, however, by the optical properties of "crystalline amylose" and Schoch's butanol precipitate before and after staining with iodine.

Another point of interest arising from dichroism of flow was that amylose-iodine solutions could be made to show dichroism of flow quite readily while amylopectin-iodine solutions did not produce this phenomenon. Amylopectin has a higher molecular weight than amylose, and failure to orient during flow must be attributed to a more nearly spherical shape. This is in agreement with a straight-chain structure for amylose and a branched structure for amylopectin.

The optical properties of both Schoch's and Kerr's material have been published by Rundle and French.³⁴ Since the optical properties of Kerr's material are more simple to interpret, and since Schoch's butanol precipitate appears to be a complex multiple crystal of similar properties, only the former will be discussed.

Kerr's crystalline amylose appears to consist of minute single crystals, at least pseudo-uniaxial in character. The flat platelets (Fig. 5) are optically negative; that is, the index of refraction is greatest for light with its electric vector in the plane of the platelet.

FIGURE 5. Crystalline amylose (Kerr, 1942).

When the small crystals are stained with iodine, they become very dichroic, but apparently remain uniaxial. Light with its electric vector normal to the plane of the platelet is very strongly absorbed, while light with its electric vector in the plane of the platelet is very weakly absorbed. From the dichroism of the iodine molecule discussed above, this would mean that the iodine molecules are arranged with their long axes normal to the plane of the platelet. If an extended-chain model is taken for the starch-iodine complex, the birefringence of the crystals would indicate that the chains lie in the plane of the platelet.* The dichroism would then mean that the long axes of the iodine molecules are normal to the long axis of the starch molecule. This is just the reverse of what was found in the dichroism of flow experiment.

* According to Silberstein's theory³⁰ the direction of greatest polarizability will be that direction in which neighboring induced dipoles will tend to reinforce each other. Light with its electric vector along the direction of greatest polarizability is retarded most.

On the other hand, the helical model provides a very satisfactory explanation of the optical properties and dichroism of flow. If the greatest polarizability of a helical starch chain is normal to the chain, then the axes of the starch helices are normal to the plane of the "crystalline amylose" platelet, and parallel to the long axes of the iodine molecule, as required by the dichroism of flow of starch-iodine solutions. The helical model also explains the uniaxial, optically negative character of the platelets which is very hard to visualize for any extended-chain model.

We see, therefore, that x-ray diffraction, dichroism of flow, the birefringence of Kerr's crystalline amylose, and dichroism of this amylose after staining with iodine all confirm closest packing of helices for "V" starch, and all are in accord with the model for the starch-iodine complex given in Fig. 4.

Swelling of the Starch Granule

The literature on the mechanism of swelling of starch granules has been reviewed in detail by Alsberg¹ and by Bear and Samsa.³⁶ A detailed analysis of the structural changes responsible for the swelling is not as yet possible.

The evidence indicates that there is no membrane or separate layer surrounding the starch granule. The unswollen granule seems to be pervious to most water-soluble electrolytes as well as to water. The forces (probably largely hydrogen bonds) within the crystallites are broken in the solution process, and enormous tangential forces are created within the granule which are released by its swelling. The insoluble tangled starch molecules, as they move outward in the swelling process, create the sac or membrane observed under the microscope. Water flows through

FIGURE 6. Swelling of potato starch granules in 2M calcium nitrate. The granule in lower center field shows maximum size of the vapor bubble (black spot) in No. 3; partial collapse of the granule is shown in No. 4. The granule in upper center field continues to swell and vapor bubble reaches maximum size in No. 8 and No. 9. Note shift in position of bubble in granule from No. 8 to No. 10 as the granule weakens and collapses to release the partial vacuum. Swelling of the granule continues after the vapor bubble disappears.

this membrane because of the reduced pressure created within the granule by the increase in volume. Conditions can be selected such that the increase in volume is more rapid than the flow of water through the periphery so that pressures within the granule are low enough for vapor bubbles to form. As the walls of the granule become less rigid because of expansion and hydration, one side of the granule will collapse, and the vapor bubble will disappear completely. A photographic record of granules passing through these stages is shown in Fig. 6.

It seems improbable that these forces are of osmotic origin. As stated by Bear, "It is difficult to believe that the relatively dilute solutions of starch of high molecular weight could very successfully compete with the concentrated calcium nitrate (2 molar) to secure water rapidly enough for the vigorous expansion observed. . . . One is almost forced to conclude that the striking swelling manifestations of starch granules are a result of an active tendency of starch chains to coil or otherwise contract, thus shortening in a radial direction and expanding tangentially as they are placed in the granule. Only in such fashion is it very easy to visualize the remarkable increases in cross-sectional area." This statement is qualified by the authors. The change from a radially extended molecule to a coiled molecule gives a mechanical picture which is possible but not essential to the phenomenon.

Starch Suspensions, Pastes and Gels

Starch products are generally used commercially as suspensions. Such systems contain swollen granules or fragments of granules which are clearly visible under a microscope. It is very apparent that the physical properties of such a system will depend primarily on the volume and physical state of the suspended phase (*i.e.*, the granules) rather than upon the composition of the granules. Samec^{4, 37} has published several summaries of the colloidal literature as it relates to starch.

The complexity of the problem can be appreciated by reviewing the factors which will affect the swelling phenomenon. It is apparent that for the different starches under a given set of conditions, swelling will be influenced by the following factors: the original size of the granule; the relative percentages of amylose and amylopectin; the size and homogeneity of the amylose and amylopectin molecules; the degree to which crystallization has taken place in the granule and the type of crystallites ("A" or "B" pattern); and whether the structure of the granule has been previously influenced by chemical or physical treatment. The recent review of the effect of dry-grinding on the physical properties of wheat starch by Lampitt, Fuller and Goldenberg³⁸ might be cited as an illustration of the complications in the practical field.

A study of the individual and combined effect of these factors remains to be made; only a few of them can be illustrated in a general way at the present time. For example, ordinary and waxy cornstarches gelatinize at the same temperature, but the range for gelatinization of the waxy starch is much narrower. The crystal patterns are almost the same, and an equal temperature potential would be required to rupture the crystal forces. Since waxy starch contains only amylopectin, the crystallite regions (and accordingly the temperature range of gelatinization) would be expected to be more homogeneous than for ordinary cornstarch with 21 per cent of amylose. The tuber starches, in the "B" configuration, all gelatinize at lower temperatures than the cereal starches in the "A" configuration. Data obtained by Sair and Fetzer³⁹ indicate that the more easily gelatinized "B" starches can be partially changed to the less easily gelatinized "A" starches while still in granule form, and that the temperature range of gelatinization changes accordingly.

In the cereal starches, and particularly in retrograded starches, the crystal forces may be so great that they cannot be broken by boiling water alone. Agents which affect hydrogen bonding, such as alkali, will assist in peptizing such aggregates. Mullen and Pacsu⁴⁰ have shown that pyridine-water solutions of suitable concentra-

tion practically obliterate the differences of gelatinization temperature shown by the starches.

The work of K. Meyer⁷ shows that at least a portion of the amylose chains are leached out of the granule at temperatures as low as at the beginning of gelatinization. The less soluble amylopectin would remain behind to form the granule residue, as explained above under the discussion of the mechanism of swelling. Upon cooling, the amylose chains and portions of the amylopectin molecules would orient and crystallize. The cooled paste would then become a magma of granule residues interlaced by crystallite regions. The cloudiness of cereal starch pastes is due to such crystallite areas. If these regions were sufficiently numerous the cooled paste would have the properties of a true solid as contrasted to a viscous sol. The measurement of elasticity or rigidity on such systems often gives greater differentiation than viscosity measurements. The contrast between cornstarch and waxy cornstarch is particularly striking.

While the role of amylose is very clear in explaining the differences between the waxy and ordinary cornstarch, there is danger in attempting to explain starch properties on the basis of composition only. For example, the waxy starches can be used for many of the purposes formerly supplied by tapioca,⁴¹ "Minute Tapioca" being a particular example. Yet tapioca starch has about 17 per cent amylose, only slightly less than ordinary corn or potato starch (22 per cent). As stated above, the properties of starch pastes must be considered as due mostly to the volume and state of the dispersed phase. From the foregoing discussion, it is evident that composition, while not the only factor to be considered, is important, as it influences the tendency of the granule to swell, rupture, or recrystallize on cooling.

Industrial control of starch products is based largely on measurement of flow properties, the fluidity funnel being the commonest type of instrument. A recent analysis of the different methods of expressing viscosity as applied to starch has been published from this laboratory.⁴² The use of hot rather than cold viscosities is recommended to avoid the complicated changes in physical state introduced by cooling. The accumulated evidence indicates that such measurements can be made with a high degree of precision in spite of their empirical character and that accurate control of the conditions for preparing the paste is more important than the type of instrument used in its measurement.^{43, 44} As indicated above, starch pastes of sufficiently high concentration become solid in character upon cooling, whereupon the measurement of elasticity or rigidity is recommended.⁴⁵

Enzymatic Action as Related to Starch Structure

Detailed reviews on enzymatic degradation and synthesis of starch and glycogen have been given by Samec,⁴⁶ Hanes² and Cori.⁴⁷ The older literature is complicated by the fact that mixtures of enzymes were frequently used, as well as by inadequate technics for evaluating the digestion products. Likewise, the use of poorly dispersed starch for the enzyme digestions led to mistaken conclusions. The following statement is limited to three types of enzymes which have been of particular importance to the problems of starch structure.

β -Amylase. This enzyme is presumed to attack at the non-reducing end, or ends, of the starch molecule and cleave off maltose groups in succession until a linkage other than the 1,4-glucosidic bond is encountered.^{2, 48} Thus straight chains like those of amylose and amylopectin are almost completely converted to maltose. Branched molecules, *e.g.*, glycogen or amylopectin, are digested only up to the points of branching. The residual "limit dextrin," according to Meyer, Wertheim, and Bernfeld,⁴⁹ possesses as many end groups as there were in the original molecule. After the α -1, 6 linkages have been hydrolyzed by an α -glucosidase, β -amylase action again proceeds.¹⁹ The results of β -amylase digestion were used extensively by Meyer in arriving at the proposed structures for glycogen⁵⁰ and for starch molecules.⁹ He

emphasizes that the starch fractions must be molecularly dispersed by solution in alkali and an excess of enzyme added immediately after neutralization to provide for complete digestion before retrogradation sets in. Soybeans provide an excellent source of pure β -amylase, since they contain relatively small amounts of other amylases.⁵¹

Schardinger enzyme. An enzyme from *Bacillus macerans* acts on starch to produce about 55 per cent of the Schardinger dextrins.⁵² The two chief reaction products, the α - and β -dextrins, are ordinarily formed in a ratio of about 3 to 1, but if a preserving agent such as trichloroethylene or benzene is added, the product consists almost entirely of the β -dextrin. The molecular weights of the Schardinger dextrins have been accurately determined by x-ray diffraction and crystal density measurements. The β -dextrin (or "cycloheptaamylose") contains seven glucose residues per molecule bonded into a ring by 1,4-glucosidic linkages; the α -dextrin ("cyclohexaamylose") is similar in structure but contains six glucose units.⁵³ The lower molecular weight values previously reported by Freudenberg and Jacobi⁵⁴ were based on cryoscopic measurements.

The enzyme apparently cleaves groups of six or seven glucose units at a time from the end of the molecule and simultaneously forms them into a non-reducing ring. It follows that molecules which do not present a chain of at least 6 or 7 unbranched glucose residues would not be attacked by the Schardinger enzyme. *B. macerans* digests starch to about the same extent as does β -amylase, presumably because both begin at the non-reducing ends of the molecule and are halted by the branched points.

Phosphorylase. Cori⁵⁵ has synthesized both starch and glycogen by the action of phosphorylase on glucose-1-phosphate. Synthetic starch produces the same x-ray diffraction pattern as native starch^{56, 57} but differs from it in consisting chiefly of the straight-chain rather than the branched type of molecule.* Evidence for the latter statement was obtained by Hanes,⁵⁸ who found that synthetic starch is completely converted to maltose by β -amylase, by Hassid and McCready⁵⁹ using methylation techniques, and by Bates, French and Rundle¹⁸ using the potentiometric iodine titration described above. The iodine titration curve as well as the specific viscosity in ethylene diamine (Fig. 3) indicate that the chain length of synthetic starch, as usually prepared, is considerably less than that of amylose from native starches. In fact, Haworth,⁶⁰ by methylation and end-group assay, arrived at a value of 80-90 glucose units for the chain length. Hassid and McCready⁵⁹ failed to detect any tetramethyl glucose in an end group assay on synthetic starch, but a small percentage could have been overlooked due to the small sample analyzed.

Another enzyme often applied to starch is α -amylase. The mechanism of its action has not been clarified sufficiently for it to be of much value in structural studies on starch. Hanes² proposed a helical configuration for the starch molecule having six glucose units per turn, partly on the basis of his belief that α -amylase produced dextrins six glucoses in length from starch. Meyer⁶¹ has recently studied the action of α -amylase on amylose and concluded that this enzyme breaks the chain at random; the longer chains are hydrolyzed most rapidly and a difficultly hydrolyzed trisaccharide remains. He believes that branching does not stop α -amylase as it does β -amylase.

SUMMARY

Starch chemistry has undergone revolutionary changes in the last few years, due in large part to the realization that starch consists partly of branched and partly of

* The reader is referred to a current review by K. Meyer ("Advances in Enzymology III," p. 109, New York, Interscience Publishers, 1943) for a discussion of the synthesis of branched chain starches and glycogen. See also Rundle, Daasch, and French, *J. Am. Chem. Soc.*, **66**, 130 (1944).

straight-chain molecules. Methods of separating the branched from the unbranched molecules in a fairly clean-cut manner have been devised and techniques for investigating them are rapidly being developed.

This review attempts to bring together recent pertinent literature on the different phases of starch chemistry, supplementing it with related material from this laboratory. Several advances of major importance, which have not been included in previous reviews of this type, are discussed, *e.g.*, evidence for the helical configuration assumed by amylose molecules in complex-formation with iodine and with butanol and the alcohols; a rapid method for determining the relative proportion of unbranched material in starch; and determination of the correct molecular weights for the Schardinger dextrans.

The advances are too recent for proper evaluation and there is a tendency to place exaggerated emphasis on certain phases of the problem. It can be said, however, that for the first time it is becoming possible to interpret and predict the behavior of starch to a limited extent on the basis of its structural composition. Rapid progress in this field is to be expected in the future.

Enzymes and the Biological Action of Vitamins

A. E. AXELROD AND C. A. ELVEHJEM

Department of Biochemistry, University of Wisconsin, Madison, Wisconsin

Introduction

The concept of vitamins as "bio-catalysts" or as component parts of "bio-catalysts" is now generally accepted. Such a viewpoint is a necessary corollary of the fact that only trace amounts of vitamins are required in the diet in order to maintain the normal functioning of the organism. It is quite apparent, therefore, that vitamins by their very nature must serve as "catalysts" for certain vital processes. We propose in this review to summarize the evidence which substantiates the thesis that "enzyme catalysis" is the most rational explanation of the biological action of vitamins.

Before entering into a discussion of such evidence, it may be well to review briefly some of the earlier concepts of the function of vitamins. The first recognition of their biological action undoubtedly was the discovery that certain foodstuffs exerted profoundly beneficial effects upon various pathological states. Thus, the observation that an abundance of liver was a remedy for night blindness, or that green vegetables or fresh-fruit juices gave relief in scurvy were early examples of such biological activity. However, very little thought was given by the first observers to the mechanism by which these responses were effected.

Nevertheless, the pioneer workers in the field of vitamins did propose a number of theories to account for the symptoms which they observed in their deficient animals. It was very natural for anyone working in that period, *i.e.*, the close of the last century, to ascribe these symptoms to the presence of pathogenic microorganisms, since the work of Pasteur and others seemed to indicate that every disease must have a positive, causative agent. However, Eijkman's⁵⁹ experimental evidence led him to abandon the theories that beriberi might be due to the presence of pathogenic organisms in rice, to lack of mechanical stimulation of the intestine, or to insufficiency of total food. He believed that the excessive metabolism of starch resulted in toxic agents which produced the symptoms of beriberi, and he suggested that the silver skin of the rice contained a substance which counteracted these toxic products. Later Eijkman⁶⁰ was led to agree with Grijn's conception of beriberi, namely, that there is present in rice polishings a substance indispensable to health.

The early concept that the symptoms of a deficiency disease were due to toxic agents in certain constituents of the diet was also proposed by Hart, *et al.*¹⁰⁸ to explain their results with calves fed rations which were balanced from restricted sources. Later, these authors were able to show that the symptoms observed by them in their early experiments were due to a lack of vitamin A in the ration. Another example of such toxicity theories is given by the comparatively recent studies on the so-called "egg-white-toxicity" syndrome observed when animals are fed raw egg-white. It was generally held by workers in this field that the egg-white contained a positive toxic factor, but Parsons, Lease and Kelly¹⁸⁴ early concluded that the injury involved an interrelation between a positive toxicity and a relative absence of a protective factor.

It is now recognized through the work of György *et al.*¹⁰¹ that the egg-white combines with biotin in the intestinal tract, and that the syndrome of egg-white toxicity is actually due to biotin deficiency.

In summary, it is now generally agreed that pathological conditions due to faulty nutrition are intrinsically caused by the *lack* of one or more necessary food constituents.

The study of tissues from vitamin-deficient animals constituted another approach toward the elucidation of the mechanism of vitamin action. A large body of literature has accumulated on this subject, and much is now known concerning the effect of various vitamin deficiencies upon the intimate structures of certain tissues. However valuable such studies may be, it is an apparent fact that such histological observations are to a great extent descriptive in nature. The fundamental changes underlying these structural modifications will be elucidated only when our knowledge of the metabolic disturbances resulting from the vitamin deficiency is much more complete.

A possible functional relationship between vitamins and hormones has been offered as an attractive hypothesis for the explanation of vitamin action. Unfortunately our information on this subject is far too meager to allow any clear-cut establishment of such relationships. However, it is most logical to assume that such relationships will be demonstrated when more is known about the specific action of both hormones and vitamins. There are many close analogies between vitamins and hormones; and if, with Green,⁹⁹ we are willing to accept the consideration that hormones are potential enzymes or prosthetic groups of enzymes, the relationship between vitamins and hormones becomes even more plausible.*

As has been indicated, the problem of the biological action of vitamins has been approached from a variety of viewpoints. It is our belief, however, that the most fundamental approach has resulted from the recent identification of some of the vitamins as components of the prosthetic groups of certain enzymes. The role of the vitamins in many of the metabolic processes of the body has thus been brought to the fore. There is ample evidence to favor the view that the biological action of vitamins is intimately related to this ability to serve as precursors for the prosthetic groups of enzymes. The acceptance of such a relationship has constituted one of the most significant steps toward our ultimate understanding of the biological action of vitamins.

Thiamine

The existence of a relationship between thiamine and carbohydrate metabolism was first recognized by Funk,⁸⁴ who suggested that the severity of thiamine deficiency symptoms could be correlated with the amount of carbohydrate in the diet. Evans and Lepkovsky⁷⁴ were the first to show definitely that rats can be maintained with greatly reduced thiamine intakes when the ration contains high levels of fat. This subject has been reviewed by Salmon and Goodman.¹⁹⁸ Using a more improved ration, Stirn *et al.*²¹⁵ have shown that the thiamine deficiency syndrome in the rat may be alleviated by the isocaloric replacement of the carbohydrate component of the thiamine-free ration by natural fats or synthetic fatty acid esters. On the other hand, Westenbrink²⁵⁰ was unable to demonstrate a reduced thiamine requirement in pigeons fed high-fat diets. Arnold and Elvehjem¹⁰ have shown that the nutritional requirement for thiamine in the case of rats, chicks and dogs may be accurately expressed in terms of the carbohydrate content of the ration. The "sparing action" of fat on the thiamine

* "Hormones and vitamins are considered together because they both represent substances whose presence in minute amounts is essential to the normality of development and function in plants and animals . . . their peculiar actions may, in some cases at least, prove to be due to their modification of biocatalysts or surfaces or to the production of changes in the permeability of tissues or membranes. Such mechanisms would permit minute amounts of materials to exert a profound influence on metabolism and function." J. Alexander. "Colloid Chemistry," 4th edition (D. Van Nostrand Co., 1937), p. 360 of Chapter XX.

requirement and the correlation between thiamine requirement and carbohydrate intake suggest that, although thiamine is not required for the catabolism of fat, it is intimately bound up with some fundamental stage in the degradation of carbohydrate. These nutritional studies have been of value in suggesting that the biological action of thiamine is related to its role in carbohydrate metabolism. However, the elucidation of the more precise function of thiamine has been derived from *in vitro* studies with surviving tissues.

From such studies definite indications that thiamine is related to carbohydrate metabolism came from the observations of Gavrilescu and Peters,⁸⁷ who, working with pigeons, showed that the respiration of brain tissue in the presence of glucose was significantly lowered in cases of thiamine deficiency. This observation gained in significance when it was demonstrated later that the *in vitro* addition of a few micrograms of thiamine markedly stimulated the oxygen uptake of polyneuritic pigeon brain in the presence of lactic acid. These workers concluded that thiamine functioned in the lactic acid oxidase system of pigeon brain. This viewpoint was abandoned, however, following the observations of Birch and Mann⁸⁹ that the coenzyme for lactic acid oxidation did not contain thiamine, and those of Meikeljohn and co-workers¹⁷¹ that an increased oxygen uptake caused by the addition of thiamine to polyneuritic brain tissue was not accompanied by an increased removal of lactic acid. When pyruvate was employed as a substrate, the addition of thiamine stimulated both oxygen uptake and pyruvate removal.¹⁸⁷ The experimental work of Elvehjem and co-workers^{201, 202, 150} verified and extended these results to other tissues, such as liver, kidney, and heart. A decrease in the respiration of liver from thiamine-deficient animals was observed even when the complicating factor of inanition was removed by forced feeding. It was proposed that thiamine was essential in all the tissues studied and that polyneuritis is a disease involving the derangement of the carbohydrate metabolism of the entire organism, rather than of the nervous tissue specifically.

There is thus ample evidence that thiamine is related to pyruvate metabolism *in vitro*. It was very desirable to have the *in vivo* confirmation of such results. This was not long in coming. The lactic acid content of polyneuritic tissues is higher than that in normal tissues, especially after exercise.^{121, 79} Light muscular work by thiamine-deficient humans¹⁵⁸ is followed by an increase in blood pyruvate. This rise in pyruvate may be maintained or still further increased at the end of half an hour's rest. After the intravenous injection of pure thiamine, "resting levels" are found following a half hour's rest after light exercise. In thiamine-deficient subjects there is, therefore, a delayed recovery from the high blood level pyruvate values which result from exercise. Results similar to the above were obtained with lactic acid by Inawashiro and Hayasaka¹¹⁵ for patients with beriberi and dogs with thiamine deficiency. Fisher⁷⁹ also found a delayed removal of lactic acid from the heart and muscles of deficient pigeons after exercise. Sherman and Elvehjem²⁰³ showed that polyneuritic chicks were unable to remove injected pyruvate from the blood as rapidly as did normal birds. Increased amounts of pyruvate were found in body fluids of human cases of fulminating, and in a number of cases of subacute beriberi.¹⁸⁹ A marked effect of thiamine upon the reduction of the pyruvate level was observed. Increased blood pyruvate values in thiamine-deficient rats and pigeons²³² and in rats, rabbits and humans¹⁵⁷ have been noted. A rapid increase in pyruvic acid content of urine occurs in rats on a low-thiamine diet.²⁰⁴ The administration of thiamine brings this level back to normal within 24 hours. The isocaloric substitution of fat for sucrose in the diets fed to thiamine-deficient rats resulted in only a partial return to normal of urinary pyruvate values. Banerji and Harris²⁴ observed that thiamine-deficient rats excreted large amounts of bisulfite-binding substances in the urine; the quantity of these was proportional to the degree of the deficiency. Harper and Deuel¹⁰⁵ observed that the excretion of pyruvate in the urine increases as the deple-

tion of thiamine reserves proceeds. Urinary pyruvate is reduced by optimal thiamine administration. At variance with the data of Shils *et al.*,²⁰⁴ Banerji²³ found that the ingestion of high-fat diets by rats deprived of thiamine resulted in a diminished excretion of bisulfite-binding substances in the urine.

The above evidence is conclusive in its demonstration that thiamine is concerned with carbohydrate metabolism, and more specifically with the metabolism of pyruvic acid, an intermediate product in the breakdown of carbohydrate.

Such was the status of our knowledge of the biological action of thiamine when in 1937 Lohmann and Schuster¹⁵⁵ demonstrated in a now classic paper that cocarboxylase is the pyrophosphoric acid ester of thiamine. Our present understanding of the biological activity of thiamine stems largely from this observation.

In 1911 Neuberg and Hildesheimer¹⁷⁷ reported the presence in yeast of an enzyme called carboxylase which catalyzed the decarboxylation of α -keto acids according to the equation:

where R is a simple aliphatic radical. In 1932, Auhagen¹¹ demonstrated that the enzyme carboxylase consisted of two components, a protein and a thermostable part called cocarboxylase. Both factors were required for the complete activity of the enzyme. Previous to this observation of Auhagen's, Kinnersley and Peters¹²⁰ in 1928 claimed that there was a form of thiamine precipitable by lead acetate. The structure of cocarboxylase was given by Lohmann and Schuster as:

It is interesting to note that Simola²⁰⁸ in 1932 observed that the cocarboxylase content of tissues from rats suffering from a complicated vitamin B deficiency was significantly lowered.

Very recently Green and co-workers⁹⁵ isolated carboxylase from top brewers' yeast in highly purified and stable form. The enzyme was found to be a diphosphothiamine-magnesium-protein. Their best preparations contained 0.46 per cent diphosphothiamine and 0.13 per cent magnesium. Green *et al.*⁹⁸ have obtained a crude pyruvic acid and α -ketoglutaric acid carboxylase from various animal tissues. This enzyme was found to consist of (1) protein, (2) a divalent cation (manganese or magnesium), and (3) diphosphothiamine. The authors suggest that this enzyme system is similar to, but apparently not identical with, that prepared from bacteria by Silverman and Werkman.²⁰⁷

The recognition of the relationship between thiamine and cocarboxylase has been the impetus for a considerable amount of work which has been conducted mainly along the following lines: (1) the relative distribution of thiamine and cocarboxylase in various cellular types; (2) the comparative biological activity of thiamine and cocarboxylase; (3) the mechanism of the enzymatic phosphorylation of thiamine to cocarboxylase; (4) the mechanism of the action of cocarboxylase; (5) the cellular reactions in which cocarboxylase is involved.

(1) **The relative distribution of thiamine and cocarboxylase in various cellular types.** The available evidence favors the view that cocarboxylase is the significant form of thiamine in animal tissues and yeast. Ochoa and Peters¹⁸⁰ have shown that in some tissues, such as brain and liver, cocarboxylase appears to be predominant, while in skeletal and heart muscle there is relatively more thiamine present and in amounts which sometimes approach that of cocarboxylase. Ochoa^{178a} believes that the vitamin in pigeon breast muscle not present as cocarboxylase is very likely the monophosphoric acid ester. Westenbrink *et al.*²⁵⁴ found only traces of free thiamine in muscle. This apparent discrepancy may be due to the presence in muscle of thiamine orthophosphate which is determined by the enzymatic method (Ochoa and Peters) along with free thiamine, and by the thiochrome method (Westenbrink *et al.*) together with cocarboxylase. Westenbrink and Goudsmit,²⁵¹ using a modification of the thiochrome method for the determination of both thiamine and cocarboxylase, have reached similar conclusions. In confirmation of the early work of Simola,²⁰⁸ both groups of workers^{178a, 254} have observed that the cocarboxylase content of tissues is much reduced in thiamine deficiency. The administration of thiamine led to a marked synthesis of cocarboxylase in the liver and kidney of avitaminous animals. Approximately 90 per cent of the total thiamine in blood is in the phosphorylated form, and Goodhart and Sinclair⁹⁰ have demonstrated that all the blood cocarboxylase is found within the blood cells. Evidence was presented for a freely diffusible form of thiamine in the blood. In addition, the authors believe that there probably exists a form of thiamine in combination with protein that is not cocarboxylase and is present in serum. Hennessy and Cerecedo¹¹⁰ confirm the observation that in animal tissues there is predominantly cocarboxylase. Houston and Kon¹¹³ have demonstrated that thiamine is present in combination with protein in milk. In normal cerebrospinal fluid thiamine is in the free, unphosphorylated form.²⁰⁹ In plant tissues, thiamine appears mainly in the free state.²²⁴ However, Horowitz and Heegaard¹¹² have extracted a carboxylase from pea roots which contains cocarboxylase.

(2) **The comparative biological activity of thiamine and cocarboxylase.** The predominance of the phosphorylated form of thiamine in animal tissues argued strongly for the viewpoint that cocarboxylase is the active form. Lohmann and Schuster¹⁵⁵ proposed that such is actually the case. However, contrary to the original observation of Lohmann and Schuster, Peters¹⁸⁵ observed that the catatorulin effect (increased oxygen uptake upon addition of thiamine) of cocarboxylase with avitaminous pigeon's brain tissue is much less than that of thiamine itself. This observation was most surprising in view of the fact that thiamine was phosphorylated rapidly under the conditions of the catatorulin test. The explanation for the anomalous results observed by Peters in the catatorulin test has recently been given by Banga *et al.*²⁵ Employing finely ground suspensions of brain tissue, these workers have been able to obtain preparations which show no catatorulin effect with free thiamine, whereas a good effect is observed with cocarboxylase. It is now evident that the previous failure of cocarboxylase to give good catatorulin effects with brain brei was due to the lack of penetration of the phosphorylated vitamin to the active enzyme centers, as had been previously suggested by Peters. Brain preparations which react to free thiamine were shown to synthesize cocarboxylase in amounts which accounted for the catatorulin effect observed. Thus, the hypothesis of Lohmann and Schuster¹⁵⁵ that the active form of thiamine in animal tissues is the pyrophosphate is now considered to be proved.

In bacteria the evidence is clear that cocarboxylase rather than free thiamine is effective in the metabolism of pyruvic acid. Working with acetone-dried preparations of *B. delbrückii* washed free from cocarboxylase, Lipmann¹⁴⁴ observed that the oxidation of pyruvic acid was catalyzed by cocarboxylase and not by free thiamine.

Barron and Lyman³¹ confirmed Lipmann's studies by experiments with a variety of bacterial cells and animal tissues. They concluded that cocarboxylase acts as a catalyst for both the oxidation and dismutation of pyruvic acid.

In yeast, Lohmann and Schuster¹⁵⁵ showed that cocarboxylase and not free thiamine is the active constituent of the carboxylase system. This observation has since been confirmed by a number of workers.^{213, 225, 151, 152, 95} Ochoa and Peters¹⁸⁰ have reported that thiamine as well as the monophosphoric acid ester stimulates the decarboxylation of pyruvic acid by alkaline-washed yeast in the presence of cocarboxylase. The action is due to the pyrimidine half of the molecule, containing the amino group. Lipton and Elvehjem¹⁵³ have questioned the physiological significance of this activation by free thiamine. Peters¹⁸⁶ has stated that this "activation" effect is an artifact. The explanations offered by various workers for this stimulatory effect of thiamine upon cocarboxylase activity will be discussed in a later section of this paper.

(3) **The mechanism of the enzymatic phosphorylation of thiamine to cocarboxylase.** The enzymatic phosphorylation of thiamine to cocarboxylase has been demonstrated in a large variety of bacterial, yeast and animal cells.^{223, 73, 155, 186, 206, 34, 151, 152, 91, 178, 247} Lipschitz *et al.*¹⁵¹ demonstrated that an aetiozymase preparation (alkaline-washed dried brewers' yeast) was able to convert thiamine into cocarboxylase in the presence of hexosediphosphate and boiled tissue extracts. A search for the thermostable constituents present in the boiled tissue extract which were necessary for this phosphorylation revealed that the synthesis of cocarboxylase could be readily achieved if cozymase and acetaldehyde were substituted for the boiled tissue extract. This synthesis was completely blocked by .003*M* sodium iodoacetate, and it was inhibited to the extent of about 50 per cent by the addition of .04*M* sodium fluoride. The authors were led to the hypothesis that the synthesis occurs as a result of the dismutation between triose phosphate and acetaldehyde, coupled with the esterification of inorganic phosphate.¹⁵³ It was also noted that the phosphorylation of thiamine could be accomplished through the dephosphorylation of phosphopyruvic acid resulting from added phosphoglyceric acid. Cozymase was not required for the synthesis under the latter conditions. Thus, two mechanisms for the phosphorylation of thiamine were indicated. Evidence was also presented to show that thiamine is phosphorylated by means of the phosphate-transferring reactions of the Embden-Meyerhof scheme with the intervention of the adenylic acid system. Ochoa and Peters¹⁸⁰ have criticized the results of Lipton and Elvehjem on the basis of their observation that free thiamine exerts a powerful stimulatory effect upon the activity of small amounts of cocarboxylase. This divergence in opinion has been satisfactorily explained by Lipton and Elvehjem.¹⁵⁴ It was demonstrated that the activation of cocarboxylase by thiamine is dependent upon the type of yeast employed. Brewers' yeast shows little activation, but bakers' yeast exhibits a strong activating effect. These observations were in accord with those of Lipmann¹⁴⁷ and Westenbrink and van Dorp.²⁵³ Moreover, Weil-Malherbe²⁴⁷ succeeded in preparing a soluble yeast protein, containing the apocarboxylase, which was activated by cocarboxylase and magnesium. This system was not stimulated by thiamine. Westenbrink *et al.*²⁵² have detected the presence of a powerful phosphatase in the yeast, capable of hydrolyzing the phosphoric acid esters of thiamine, and explained the stimulation of the carboxylase system by thiamine as being due to the inhibition of the action of this phosphatase by free thiamine. Lipton and Elvehjem¹⁵⁴ offer an alternate explanation for the thiamine activation observed in their samples of bakers' yeast. They suggest that there is a heat-labile material in bakers' yeast which can adsorb cocarboxylase without the production of an active enzyme. The addition of excess thiamine saturates this material and thus permits the adsorption of the cocarboxylase upon the active apoenzyme. In confirmation of Lipton and Elvehjem,¹⁵³ Weil-Malherbe²⁴⁷ was also able to show that the phosphorylation of thiamine was performed by phosphate trans-

fer from adenosine triphosphate to thiamine. This phosphate transfer is apparently effected only at the surface of the carboxylase protein, since the synthesis stops as soon as the carboxylase protein becomes fully saturated. Phosphopyruvic acid could act as a phosphate donator for the synthesis of cocarboxylase in the presence of catalytic amounts of adenylic acid or adenylypyrophosphate. Thiamine monophosphate was found to be slightly inferior to thiamine as a precursor of cocarboxylase. This was interpreted as meaning that the monophosphate is not an intermediary of the synthesis, but must first be hydrolyzed to free thiamine.

The data of Lipton and Elvehjem, Weil-Malherbe, and Lohmann and Schuster all indicate that the synthesis of cocarboxylase from thiamine requires the intermediation of adenosine triphosphate. It is then to be expected that the phosphorylation of thiamine by inorganic phosphate is intimately connected with simultaneous dismutations or oxidations involving the catalysis by coenzymes. This viewpoint is in accord with the data of Ochoa¹⁷⁸ who, in a study of the enzymic synthesis of cocarboxylase in animal tissues, concluded that the phosphorylation of thiamine is enhanced when energy from intact respiration is available. Ochoa's failure to obtain increased synthesis with liver preparations on addition of adenosine triphosphate, phosphoglyceric acid, or both together, argues against a direct transfer of phosphate from either compound to thiamine.

(4) **The mechanism of the action of cocarboxylase.** The identification of cocarboxylase as thiamine pyrophosphate suggested two explanations for the mechanism of the catalytic activity of cocarboxylase: (1) a "Langenbeck cycle" involving the amino group in the pyrimidine ring, or (2) a reversible oxidation and reduction of the double bond adjoining the quaternary nitrogen in the thiazole nucleus.

Langenbeck¹⁴¹ has shown that primary amines are capable of decarboxylating α -ketocarboxylic acids. The reaction is depicted in the following manner:

From these observations, Langenbeck predicted that a primary amino group would be found at the active center of the carboxylase molecule. The elucidation of the structure of cocarboxylase appeared to confirm this hypothesis. Further support for Langenbeck's hypothesis was derived from the work of Bergel and Todd⁸⁷ and of Cline,⁴⁶ showing that hydroxythiamine has no biological activity. Cline⁴⁷ observed that replacement by alkyl groups of one or both hydrogen atoms of the amino group in the pyrimidine moiety results in a very marked reduction in the vitamin potency.

Stern and Melnick²¹⁴ examined the Langenbeck hypothesis in great detail and their evidence suggested the view that pyruvic acid is not decarboxylated via the "Langenbeck cycle." Their evidence, in brief, consisted of the observations that thiamine is not a typical primary amine and that, in the test system of Langenbeck, thiamine was found to be completely inactive as a carboxylase model. Weil-Malherbe²⁴⁸ has suggested in support of the Langenbeck cycle that the properties of the amino group may be profoundly altered in the combination of cocarboxylase with the protein. Barron⁸¹ prefers to believe that the combination of cocarboxylase with pyruvate may take place at the amino group and that the pyruvate thus activated may react with catalysts for its oxidation, reduction, dismutation or condensation. Weil-Malherbe²⁴⁹ has proposed the following hypothesis for the catalytic activity of cocarboxylase. His theory is founded on the fact that cocarboxylase possesses a free amino group and, in addition, contains a pentavalent nitrogen atom which may be capable of alternate oxidation and reduction. Briefly, the initial steps in the decar-

boxylation of α -ketocarboxylic acids involve intramolecular oxidation-reduction of the Schiff base primarily formed:

In animal tissues, III would be oxidized to acetyl diphosphothiamine, whereas in yeast a second intramolecular oxidation-reduction would occur, resulting in the Schiff base of acetaldehyde (IV). Evidence that cocarboxylase does not act as a sluggish reversible oxidation-reduction system argues against this theoretical proposal of Weil-Malherbe.

Lipmann and Perlmann¹⁴⁹ have shown that thiamine may be reduced by $\text{Na}_2\text{S}_2\text{O}_4$ or Pt-H_2 . Cocarboxylase is also reduced by $\text{Na}_2\text{S}_2\text{O}_4$.³⁵ As pointed out by Barron,²⁸ it is quite possible that during the reduction process with $\text{Na}_2\text{S}_2\text{O}_4$ the thiamine molecule is split into pyrimidine and thiazole. The reduction of thiamine and cocarboxylase was confirmed by Stern and Melnick.²¹⁴ It was suggested by Lipmann¹⁴⁵ that thiamine acts as a sluggish reversible oxidation-reduction system. Lipmann¹⁴³ postulated a two-step reduction, and contended that an intermediary semiquinoid radical was formed in the reaction. There is, however, no evidence at the present which proves that cocarboxylase undergoes a cycle of oxidation and reduction during its catalytic activity. In fact, Barron and Lyman^{35a} have shown that thiamine becomes, with phosphorylation, more resistant to the action of reducing and oxidizing agents.

It must be concluded that the mechanism of the catalytic activity of cocarboxylase remains unknown.

(5) **Reactions catalyzed by cocarboxylase.** It is apparent that a complete understanding of the reactions catalyzed by cocarboxylase is dependent to a great extent upon a detailed knowledge of the metabolic pathways of pyruvic acid. Pyruvic acid is an extraordinarily reactive compound. It is the key compound in most forms of carbohydrate breakdown, in transamination, in the formation of ketone bodies, and in many other biological reactions.

In yeast, cocarboxylase functions simply in the decarboxylation of α -ketocarboxylic acids to carbon dioxide and the corresponding aldehyde. In animal and in many bacterial species this reaction apparently does not occur. The reactions catalyzed by cocarboxylase in these cells are considerably more complex.

Lipmann¹⁴⁵ has studied in great detail the oxidative decarboxylation of pyruvic acid to acetic acid by *B. delbrückii*. He has found that at least five components are required for the catalysis of pyruvic acid dehydrogenation with oxygen as the hydrogen acceptor: (1) cocarboxylase; (2) flavin-adenine dinucleotide; (3) Mg^{++} , Mn^{++} , or Co^{++} ; (4) protein; and (5) inorganic phosphate. The anaerobic dismutation of pyruvic acid in these bacteria involves riboflavin as the coupling link. The dismutation is a "fermentation-like" reaction with pyruvic acid-pyruvic dehydrogenase as the reductant, pyruvic acid-lactic dehydrogenase as the oxidant, riboflavin acting as the hydrogen carrier between the two systems. Cocarboxylase, therefore, also func-

tions in this dismutation reaction. Barron and Lyman³⁴ have demonstrated that cocarboxylase acts as a catalyst for both the dismutation and oxidation of pyruvic acid by a number of bacterial and animal tissues. The anaerobic dismutation of pyruvic acid carried out by certain bacteria depends on the presence of thiamine.¹¹¹ The oxidation of acetate by propionic acid bacteria is also catalyzed by thiamine.¹⁹⁴ Smyth,²¹⁰ employing thiamine-deficient staphylococci, has given evidence in support of the proposal of Krebs and Eggleston¹³² that thiamine catalyzes the synthesis of oxalacetate from pyruvate and CO₂. Krampitz and Werkman¹³¹ have shown that cocarboxylase is not a coenzyme for the enzyme which brings about the decarboxylation of oxalacetate to pyruvate and CO₂ in *Micrococcus lysodeikticus*. These results appear to be at variance with those reported by Smyth.

Barron³¹ has reported that cocarboxylase accelerates the following reactions in animal tissues:

- (1) Carbohydrate synthesis from pyruvate where the initial reaction seems to be:
 $\text{pyruvate} + \text{fumarate} + \text{H}_3\text{PO}_4 \rightarrow \text{phosphopyruvate} + 4\text{CO}_2 + 2\text{H}_2\text{O}.$
- (2) Citrate synthesis from pyruvate and oxalacetate.*
- (3) Synthesis of succinate.
- (4) Synthesis of acetoacetate.
- (5) Oxidation of α -ketoglutarate to succinate.

The multiplicity of the reactions catalyzed by cocarboxylase is offered as evidence for the view that cocarboxylase is a catalyst not only for the oxidation and decarboxylation of pyruvate, but also for many other reactions where pyruvate is one of the reacting substances. Krebs and Eggleston¹³² propose that cocarboxylase is the catalyst for the Wood and Werkman²⁵⁹ reaction: $\text{CO}_2 + \text{CH}_3\text{COCOOH} \rightarrow \text{COOH} \cdot \text{CH}_2 \cdot \text{COCOOH}$. Their evidence for this proposal is based on a study of the rate of metabolism of pyruvate by liver suspensions under conditions where the "carboxylation" reaction was assumed to be the chief metabolic reaction for the removal of pyruvate. Under these conditions the rate of removal of pyruvate was greatly reduced in polyneuritic pigeon liver and was restored to normal by the *in vitro* addition of small quantities of thiamine. Banga, Ochoa and Peters²⁶ state that the following substances are components of the pyruvate oxidation system of brain and, probably, of other animal tissues: (1) cocarboxylase; (2) inorganic phosphate; (3) C₄ dicarboxylic acids; (4) "adenine nucleotide"; (5) Mg⁺⁺ or Mn⁺⁺; and probably (6) pyridine nucleotide.

Lipmann,¹⁴⁶ working with *B. delbrückii*, has found that the dehydrogenation of pyruvic acid is coupled with the phosphorylation of adenylic acid. If such a process were to occur in animal tissues, it would afford another source of phosphorylation energy. Ochoa¹⁷⁹ has been able to demonstrate such a coupling between the oxidation of pyruvic acid in brain tissue with phosphorylation processes. He obtained evidence in support of the view that oxidation of pyruvate is connected with phosphorylation of adenylic acid to adenosine polyphosphate which transfers its labile phosphate groups to either hexose monophosphate or glucose, with formation of hexose disphosphate. Both Lipmann's and Ochoa's work have identified the oxidation of pyruvate with the esterification of inorganic phosphate. Thus, the role of cocarboxylase as a catalyst in phosphorylation processes has become evident.

Miscellaneous Reactions in Which Cocarboxylase May Function Catalytically.

The emphasis hitherto has been laid upon the functional role of cocarboxylase in pyruvic acid metabolism. However, other metabolic reactions catalyzed by cocarboxylase deserve our attention.

Quastel *et al.*¹⁹⁵ have shown that a choline ester is formed when brain cortex slices are allowed to respire in a medium containing eserine. Stedman and Stedman²¹² have subsequently isolated acetyl choline from minced ox brain. It is of in-

* These results verify the conclusions of Sober, Lipton and Elvehjem²¹¹ that cocarboxylase is essential for the synthesis of endogenous citric acid from its precursors.

terest to note that the rate of formation of acetyl choline was greatest when substances such as glucose, sodium lactate and sodium pyruvate were present in the medium under aerobic conditions. There was no accumulation of acetyl choline under anaerobic conditions. With our present knowledge of the pyruvate oxidase system of brain it becomes easy to visualize the necessity for the formation of an energy-rich acetyl intermediate (perhaps acetyl phosphate from the oxidation of pyruvate) for the acetylation of choline. In fact, Mann and Quastel¹⁵⁹ have demonstrated that the rate of synthesis of acetyl choline with pyruvate as substrate is greatly diminished in polynuritic brain tissue. The addition of thiamine to the polynuritic brain restored the synthesis to normal. Hence, the action of thiamine on acetyl choline synthesis is linked with pyruvate metabolism, and acetyl choline synthesis may represent but another outlet for the energy derived from the oxidation of pyruvate.

Many of the cardiac and gastrointestinal symptoms of thiamine deficiency may be relieved temporarily by the administration of choline esters. Thus, it would appear as though thiamine might be an inhibitor of choline esterase, and a deficiency of thiamine would result in an increased choline esterase activity, which in turn would lead to a lowered acetyl choline concentration. Such an interpretation may be useful in explaining the observation of McHenry¹⁶⁵ that a thiamine deficiency had a curative effect upon the fatty livers of rats kept on a low-choline diet. It has been demonstrated that thiamine exerts an inhibitory action upon choline esterase *in vitro*.^{89, 42, 218, 88 *} The ability of thiamine to augment the activity of acetyl choline in numerous test systems has been observed.^{40, 172, 5, 1} It is not yet clear whether thiamine acts directly upon acetyl choline or functions indirectly by its ability to inhibit choline esterase, the enzyme which hydrolyzes acetyl choline to choline and acetic acid. Support for the inhibitory action of thiamine upon choline esterase has been given by *in vivo* experiments.^{8, 9} The results of Zeller and Birkhäuser²⁶⁰ are not of a confirmatory nature.

Thiamine is liberated when cholinergic nerves are stimulated electrically.¹⁷³ Since choline is liberated as the acetyl compound, Kuhn *et al.*¹³⁹ have proposed that thiamine may also be liberated as the acetyl compound, and they have studied the effect of acetyl aneurin on isolated rat intestine. Acetyl aneurin, in contrast to thiamine, had an activity similar to that of acetyl choline, an observation which seemed to strengthen the validity of their hypothesis. If the nerve impulses were mediated through acetyl aneurin, one would expect that the mediator, acetyl aneurin, would be capable of rapid removal from the site of action. Since acetyl aneurin is hydrolyzed very slowly, Glick and Antopol⁸⁹ do not believe it likely that it is such a mediator.

Edlbacher and Becker⁵⁸ have observed that the liver histidase and arginase activities are greater in thiamine-deficient than in normal rats. Zeller *et al.*²⁶¹ reported that the oxidative deamination of histamine was strongly inhibited by thiamine. In accordance with this observation, the authors observed an increased histaminase activity in thiamine-deficient rats. The physiological significance of these results is obscure.

The hypothesis that thiamine is required for the synthesis of fat from carbohydrate has been advanced.¹⁶⁵⁻¹⁶⁸ The data of Longenecker *et al.*¹⁵⁶ are in agreement with such a concept. It is likely that cocarboxylase may play an important role in fat synthesis.²⁵⁶ However, the precise mechanism of such a catalysis is not clear at present.

Nicotinic Acid

The discovery of the biological activity of nicotinic acid and its relationship to the pyridine nucleotides constitutes a most absorbing chapter in the field of biochemistry.

* Cocarboxylase was less effective than thiamine in its inhibitory action.⁸⁹ Byer and Harpuder⁴² conclude that thiamine has no effect upon choline esterase activity.

The story of this vitamin affords an excellent illustration of the merging of the field of nutritional research with that of respiratory enzymes. Thus, it is undoubtedly true that the identification of the anti-pellagra factor was aided greatly by studies on the constitution of the pyridine nucleotides.

Huber¹¹⁴ first prepared nicotinic acid in 1867 by the oxidation of nicotine. The isolation of nicotinic acid from biological materials was achieved by Suzuki *et al.*²²¹ in 1912 from rice polishings, and by Funk^{82, 83} in 1913 from yeast concentrates which possessed antineuritic activity. Nicotinic acid itself displayed no activity in curing pigeon beriberi, but the results of Funk's experiments caused him to suggest that it might play a definite role in the vitamin B complex. In the light of our present knowledge, such a suggestion appears to have been based on incomplete experimental evidence. However, this was the first instance in which a definite vitamin function was ascribed to nicotinic acid. Williams²⁵⁷ in 1917 investigated the antineuritic potency of nicotinic acid, but found that it did not cause any permanent improvement in polyneuritic fowl. Continuing the work on the vitamin nature of the pyridine derivatives, Szymanska and Funk²²² observed that nicotinic acid amide had an appetite-stimulating and weight-preserving action on pigeon beriberi.

With the exception of the above-mentioned work, very little interest was shown in the possible role of pyridine derivatives in living systems until the work of Warburg and von Euler in 1935. Warburg and Christian²⁴⁰ characterized nicotinamide as one of the hydrolysis products from the coenzyme which they had isolated from blood, and which now is known as Coenzyme II. The accurate characterization of Coenzyme I quickly followed that of Coenzyme II and it, too, was found to contain nicotinic acid amide.^{241, 242, 65} Kuhn and Vetter¹³⁷ in the same year isolated nicotinic acid amide from heart muscle. Thus, a new impetus was given to the application of nicotinic acid in the field of nutrition. Euler and Malmberg,⁶⁸ using a ration very similar to the Sherman-Bourquin diet supplemented with a thiamine concentrate and riboflavin, found no growth response with nicotinic acid and its amide, although the rats receiving nicotinic acid lived longer. Funk and Funk⁸⁵ reported that rats and pigeons on certain rations showed a larger food intake and better growth when given nicotinic acid, and especially the amide. Frost and Elvehjem⁶¹ observed a growth stimulus from nicotinic acid when fed with adenylic acid to rats on a diet deficient in factor W.

The significance of nicotinic acid in the nutrition of microorganisms was also recognized at about this time.^{124, 174, 180, 76}

The earlier attempts to demonstrate the role of nicotinic acid in the animal economy cannot be considered as definite proof of the vitamin nature of this compound. The first conclusive evidence that nicotinic acid functions as a vitamin in higher animals was furnished by the demonstration that nicotinic acid or its amide was the "anti-blacktongue factor" in dogs.⁶¹ The efficacy of nicotinic acid in human pellagra is now well known; Chick *et al.*⁴³ and Harris¹⁰⁷ have demonstrated its role in the nutrition of the pig and monkey.

It is clear from the foregoing that the isolation of substances important in biological oxidations greatly influenced the nutritional research on nicotinic acid.

The fact that nicotinic acid amide is a constituent of the pyridine nucleotides led to the natural assumption that the function of nicotinic acid is related to these nucleotides (Coenzymes I and II). Before discussing the evidence for such a relationship it may be well to review briefly our knowledge of the functional role of the pyridine nucleotides in the metabolic reactions of the organism. This subject has been adequately discussed in a number of review papers.^{86, 21, 190, 63, 238, 77, 52, 163, 93, 183}

Diphosphopyridine nucleotide (cozymase, Coenzyme I) is found in a large variety of plant and bacterial species and is present in practically all animal tissues. Triphosphopyridine nucleotide (Coenzyme II) is also widely distributed in cells. It is safe to make the generalization that most metabolizing tissues contain these nucleo-

one metabolite to be oxidized by the oxidized form of another metabolite of higher potential. Thus, certain dehydrogenase systems can be "linked" with others by means of the pyridine nucleotides.^{51, 175, 97, 245} As an example, the hydroxybutyrate-acetoacetate and oxaloacetate-malate systems may be "linked" by diphosphopyridine nucleotide in the following manner:

This type of reaction makes it conceivable that all the metabolites which can react with the pyridine nucleotides are in constant dynamic equilibrium with one another. The fundamental role of diphosphopyridine nucleotide in alcoholic fermentation and in glycolysis in animal tissues is discussed by Baumann and Stare³⁶ and Ball.²¹ In addition to its action as a hydrogen carrier, diphosphopyridine nucleotide may also function in the transfer of phosphate. Thus, Ohlmeyer and Ochoa¹⁸² have shown that diphosphopyridine nucleotide is an intermediate in the transfer of phosphate from phosphopyruvic acid to glucose.

The possible function of the pyridine nucleotides in protein metabolism as well as carbohydrate metabolism is discussed by Ball.²¹ The role of the pyridine nucleotides in protein metabolism is made probable by the fact that the nucleotides have been shown to be active in the oxidation of glutamic acid.⁶⁶ The interrelationships involved indicate that protein and carbohydrate metabolism may be linked through the pyridine nucleotides.

It is apparent that, by virtue of their ability to function as reversible oxidation-reduction systems, the latter play a central role in the metabolism of carbohydrates and probably of proteins. The biological importance of nicotinic acid amide is emphasized by the fact that it serves as the functional group of the pyridine nucleotides.

The *in vitro* demonstration of the relationship between the pyridine nucleotides and nicotinic acid amide has stimulated considerable interest in an effort to establish the existence of this relationship *in vivo*.

Euler and co-workers were the first to undertake a systematic investigation of this problem. A number of papers have appeared from the Euler laboratory purporting to show that both nicotinic acid and the pyridine nucleotides are dietary essentials for the rat.^{68, 64, 67, 69, 70} Their choice of the rat as the experimental animal in which to demonstrate the *in vivo* relationship between nicotinic acid and the pyridine nucleotides was an unfortunate one since it is very difficult to produce in this species an uncomplicated deficiency of the coenzymes or of any of their possible precursors. Recent evidence^{50, 205} indicates that the normal rat is fully capable of synthesizing nicotinic acid and is, therefore, not dependent upon a dietary source of this compound. Recently von Euler and co-workers⁷² found that the carcasses of rats fed diets low in the vitamin B complex tends to be lower in nicotinic acid amide and cozymase than those of normal rats. In the opinion of the reviewers, the experimental work presented by the Euler school does not offer conclusive evidence of an *in vivo* relationship between nicotinic acid and pyridine nucleotides. However, the existence of such a relationship in the rat has been indicated by Katzenelbogen *et al.*¹¹⁶ These workers observed marked decreases in the diphosphopyridine nucleotide content of the liver and kidney cortex of hyperthyroid rats fed rations low in nicotinic acid. Supplementing such rations with excessive amounts of nicotinic acid restored the diphosphopyridine nucleotide content of these tissues to their normal values.

In other species, such as the dog, pig and human, considerable evidence has accumulated to prove definitely that the dietary intake of nicotinic acid markedly influences the coenzyme content of tissues. This demonstration has been made possible

by the fact that definite nicotinic acid deficiencies can be produced in the above-mentioned species.

Several workers have observed an increase in the coenzyme content of blood following the administration of nicotinic acid to human subjects.^{125, 234, 127, 14} The *in vitro* synthesis of the pyridine nucleotides from nicotinic acid by defibrinated human blood has also been demonstrated.^{127, 236, 18} Vilter *et al.*²³⁶ question the ability of the erythrocytes to synthesize the coenzymes, and suggest the tentative hypothesis that nucleated cells are essential for the synthesis. Kohn and Klein¹²⁸ present strong evidence to substantiate their earlier claim that human erythrocytes are capable of synthesizing the pyridine nucleotides from nicotinic acid *in vitro*.

Vilter *et al.*,^{234, 235} using *Bacillus influenzae* in a microbiological method, have reported decreases in the amount of factor V (Coenzymes I and II and possibly other related substances) in the whole blood of pellagrins. On the other hand, Kohn and Bernheim,¹²⁶ using *Haemophilus parainfluenzae*, did not find any significant decreases in the factor V of the erythrocytes from the blood of pellagrins. The results of Axelrod *et al.*,¹⁸ who employed a yeast fermentation method specific for coenzyme I,¹² are in better agreement with those of Kohn and Bernheim. The conflicting results obtained by the various workers in this field can be attributed to the fact that different methods have been used both for measuring the pyridine nucleotide content and for expressing the units of concentration of these coenzymes.²³⁵ The choice of patient would also undoubtedly affect the results obtained. Ballif *et al.*²² found no reduction in the nicotinic acid amide content of the blood of ten pellagrins.

Axelrod *et al.*¹⁸ have studied the diphosphopyridine nucleotide content of striated muscle in a series of normal subjects and patients with varying degrees of pellagra. The decrease in diphosphopyridine nucleotide content which was observed in the pellagrous patients could be correlated with the severity of the deficiency. The administration of nicotinic acid to the pellagrins led to marked increases in the diphosphopyridine nucleotide content of muscle.

The coenzyme content of certain tissues of the dog has been correlated with the dietary intake of nicotinic acid. Decreases in the coenzyme content of the liver and striated muscle of dogs suffering from a nicotinic acid deficiency have been reported.^{129, 49, 188, 15} In addition, Pittman and Fraser¹⁸⁸ observed a decrease in the coenzyme content of the cardiac muscle. No significant changes were observed in the blood. Similar results in the pig have been reported by Axelrod *et al.*¹⁵

The ability of a number of microorganisms to synthesize the pyridine nucleotides from nicotinic acid has been demonstrated.^{124, 76, 64, 123}

The above data clearly demonstrate that several different species are capable of synthesizing the pyridine nucleotides from nicotinic acid. This, plus the fact that a nicotinic acid deficiency results in a decreased synthesis of the coenzymes, argues strongly for the fact that at least one of the functions of nicotinic acid is to serve as a precursor for the pyridine nucleotides in the organism. However, we must not overlook the possibility that nicotinic acid may function in a manner entirely unrelated to its role as a constituent of the pyridine nucleotides. A number of lines of evidence are available which would indicate such a multiple function of nicotinic acid.

Dorfman *et al.*⁵⁵ have grown dysentery bacilli on a medium containing suboptimum amounts of nicotinic acid, and have observed that both the rate of reduction of methylene blue and the respiration rate of these bacterial cells are greatly increased, not only by the addition of diphosphopyridine nucleotide but also by the addition of nicotinamide or nicotinic acid. Dorfman *et al.*⁵³ have further found that nicotinamide is more active in stimulating the growth of the dysentery bacillus than an equivalent amount of either diphosphopyridine nucleotide or triphosphopyridine nucleotide. These results were taken as evidence to indicate that the function of nicotinic acid amide was not based entirely on its ability to serve as a constituent of the coenzyme molecule. However, alternate explanations could be based upon: (1) the ability of

the cell to synthesize the coenzymes from nicotinic acid, and (2) the varied permeability of the cell to nicotinamide and to the pyridine nucleotides. In a later paper, Saunders *et al.*¹⁹⁹ have presented evidence which appears to invalidate the objections which have been raised to the conclusions derived from their earlier work. The authors have suggested that nicotinamide may function as a constituent of a nicotinamide ironporphyrin which is capable of serving as a respiratory catalyst.³² The results of McIlwain support the contention that nicotinamide may function as a respiratory catalyst distinct from the pyridine nucleotides.¹⁷⁰ He observed that the growth of *Proteus* promoted by diphosphopyridine nucleotide is much more strongly inhibited by pyridine-3-sulfonic acid than that promoted by nicotinamide. Similar results were obtained with *Staphylococcus*.

Another type of evidence is available which would suggest that a nicotinic acid deficiency cannot be explained solely in terms of a deficiency of the pyridine nucleotides. Thus, in the nicotinic acid-deficient dog, Kohn *et al.*¹²⁹ could not correlate the appearance of deficiency symptoms with the coenzyme content of various tissues. Furthermore, these authors could find no consistent relationship between the coenzyme content and the oxidative metabolism of isolated tissues. These experimental data prompted the suggestion that nicotinic acid enters the metabolism in essential ways as yet unknown. From an experimental standpoint any attempt to establish such correlations must admittedly be beset with many difficulties, and more work is necessary in this field before any definite conclusions concerning the role of nicotinic acid can be made. In their work with humans, Axelrod *et al.*¹⁸ have determined that the antipellagric value of a compound is not necessarily associated with its ability to affect the diphosphopyridine nucleotide content of tissues. Thus, treatment of pellagrins with pyrazinemonocarboxylic acid and coramine resulted in a definite clinical improvement, which was not accompanied by consistent changes in the diphosphopyridine nucleotide content of erythrocytes or muscle. These compounds were also unable to effect an *in vitro* synthesis of diphosphopyridine nucleotide by defibrinated blood.

Dann and Handler⁴⁹ have reported that in certain organs of the dog a considerable proportion of the total nicotinic acid is present in the "free" form, *i.e.*, not as a component of the coenzymes. In blacktongue, the coenzyme level falls, but the "free" nicotinic acid is not considerably affected. This would suggest an important role for this "free" fraction of the total nicotinic acid distinct from its relationship with the pyridine nucleotides.

Mann and Quastel¹⁶⁰ have proposed still another mechanism for the biological activity of nicotinamide. They have observed that the rapid inactivation of diphosphopyridine nucleotide by brain and liver tissue is inhibited by nicotinamide, and they draw attention to the possibility that the therapeutic effects of nicotinamide may be due partially to its protective effects on diphosphopyridine nucleotide breakdown. To date, no experimental verification of this suggestion is at hand. The amounts of nicotinic acid amide necessary to prevent the breakdown of diphosphopyridine nucleotide *in vitro* appear to be unphysiological. However, the nucleotidase activity *in vivo* may be localized to portions of the tissue where the nicotinic acid is in fairly high concentration. This latter consideration would support the concept of Mann and Quastel.

In summary, although the role of nicotinic acid is undoubtedly related to its ability to serve as a precursor of the pyridine nucleotides, it should be borne in mind that other functions for nicotinic acid remain a distinct possibility.

Riboflavin

In 1932 Warburg and Christian²³⁹ isolated from bottom yeast a yellow conjugated protein which they called the "yellow enzyme." At the same time Banga and Szent-Györgyi²⁷ prepared a concentrate of "respiration-coferment" from the heart

muscle of swine. The golden-yellow pigment present in this concentrate was named "cytoflav." The absorption spectrum of cytoflav revealed its structural similarity to Warburg's yellow enzyme,¹⁴⁰ and Kuhn and Rudy¹³⁵ showed cytoflav to be the phosphoric acid ester of riboflavin. Historically speaking, these discoveries appear to be the first steps in a long series of researches which have been necessary to establish our present concept of the close relationship between vitamins and oxidative enzymes. The story of riboflavin is also unusual, in that its isolation from natural sources and the recognition of its vitamin-like character paralleled very closely its identification as a constituent of the prosthetic group of an oxidative enzyme. The discovery of Warburg's "yellow enzyme" initiated the study of flavoproteins, and the past decade has witnessed the isolation of a large number of respiratory enzymes which contain riboflavin as a constituent of the prosthetic moiety. A resumé of this family of flavoprotein enzymes is in order, since the biological activity of riboflavin is intimately related to the enzymatic activity of the flavoproteins.

The Warburg-Christian "yellow enzyme," isolated in 1932 from bottom yeast, was the first flavoprotein to be described. The purification of this substance has been accomplished.^{226, 228, 229, 255, 184} The yellow enzyme has been reversibly resolved into the protein group and the prosthetic component by Theorell^{226, 228, 229} and by Warburg and Christian.²⁴⁴ The prosthetic group, *i.e.*, the pigment portion, was found to exist as the phosphoric acid ester of riboflavin.²²⁷ The synthesis of riboflavin-5'-phosphoric acid ester has enabled Kuhn *et al.*¹³⁶ to reconstruct the original yellow enzyme. It was postulated that the protein component of the enzyme is bound to the phosphoric acid radical and to the free imide group in position 3 of the riboflavin-5'-phosphoric acid ester.^{231, 133} The combination of protein and prosthetic group has been given as:

Further indications that the protein and prosthetic group may be linked through the isoalloxazine ring are summarized by Ball.²⁰

Research in the field of the flavoproteins was markedly stimulated by the observations of Straub²¹⁶ and of Warburg and Christian²⁴⁸ that the prosthetic group of the *d*-amino acid oxidase was a riboflavin compound not identical with any hitherto recognized. Warburg and Christian²⁴⁴ identified the prosthetic group as a riboflavin-adenine dinucleotide composed of one adenine, one riboflavin, two pentose and two phosphoric acid molecules. The compound yields adenosine-5-phosphoric acid and riboflavin phosphate on acid hydrolysis,² making it very probable that riboflavin-adenine dinucleotide is constructed through a union of flavin phosphoric acid with adenosine-5-phosphoric acid as indicated:

*Riboflavin-adenine dinucleotide*

Purification of the protein component of *d*-amino acid oxidase is described by Negelein and Brömel.¹⁷⁶

The discovery of riboflavin-adenine dinucleotide led to the isolation of a number of flavoproteins containing riboflavin-adenine dinucleotide as their prosthetic group. In some cases the riboflavin-adenine dinucleotide is associated with other groupings of unknown constitution. It should be noted that the prosthetic group of cytochrome C reductase¹⁰³ is alloxazine mononucleotide. To date, the following respiratory enzymes may be classified as flavoproteins containing riboflavin-adenine dinucleotide as their prosthetic group:

- (1) *d*-amino acid oxidase^{243, 244}
- (2) Straub's heart muscle flavoprotein²¹⁷
- (3) Milk flavoprotein *^{19, 48}
- (4) Pyruvic acid oxidase system of *B. delbrückii*¹⁴⁴
- (5) Yeast fumarate hydratase⁷⁸
- (6) Liver aldehyde oxidase *⁹²
- (7) Yeast flavoprotein of Haas¹⁰²

The biological activity of the flavoprotein isolated from top yeast by Green *et al.*⁹⁶ has not been characterized as yet. The prosthetic component of this flavoprotein consists of riboflavin-adenine dinucleotide plus an unknown group.

The most important biological role of the flavoproteins appears to be that of "respiratory mediators," *i.e.*, compounds which catalyze the transfer of electrons between sluggish oxidation-reduction systems. As "respiratory mediators" the flavoproteins function in the transfer of electrons from the pyridine nucleotides to the cytochrome system. The cytochrome C reductase of Haas, Horecker and Hogness is an outstanding example of a flavoprotein which functions in this manner. This flavoprotein catalyzes the reduction of cytochrome C by reduced triphosphopyridine nucleotide at a very rapid rate, and probably represents the physiological mechanism for the oxidation of reduced triphosphopyridine nucleotide. The milk flavoprotein of Ball, and Corran and Green; Straub's heart-muscle flavoprotein; the yeast flavoprotein of Haas; and the diaphorase preparations of Adler *et al.*⁴ also catalyze the oxidation of the reduced pyridine nucleotides. The physiological oxidants of these latter flavoproteins have not, however, been definitely determined, although it has been frequently suggested that these flavoproteins link the pyridine nucleotide systems to the cytochrome system.

The important role of flavoproteins as links between two sluggishly reversible systems was overlooked for a considerable time because the "yellow enzyme" of Warburg and Christian was autoxidizable. Thus, although the cytochrome system was absent from Warburg's original enzyme system which catalyzed the oxidation of hexosemonophosphate, the reduced "yellow enzyme" was oxidized by oxygen. How-

* The prosthetic groups of the flavoproteins marked with an asterisk contain unknown components in addition to riboflavin-adenine dinucleotide.

ever, doubt was cast upon the physiological role of flavoproteins as mediators between the pyridine nucleotides and oxygen by Theorell.²³⁰ He showed that the rate of oxidation of reduced yellow enzyme at oxygen tensions existing in animal tissues was so slow as to make it doubtful that that was the physiological pathway. Cytochrome C catalyzed the oxidation of reduced yellow enzyme, and Theorell suggested that the cytochrome system was the physiological oxidant of the "yellow enzyme." The cytochrome system has been shown to be involved in the oxidation of hexosemonophosphate by certain bacteria.²⁹ It is recognized that biological oxidations involving oxygen are inhibited by cyanide to at least 90 per cent. In the light of our present knowledge, it is quite probable that Warburg's original "yellow enzyme" is an artifact, and that flavoproteins analogous either to cytochrome reductase or to flavoproteins in which riboflavin-adenine dinucleotide is the prosthetic group, may be the true electron mediators of the cell.

The enzymatic activities of the remaining flavoproteins are summarized in Table 1.

As is the case with the pyridine nucleotide dehydrogenases, the reductants of the flavoproteins of the above table are quite clearly defined. However, the information relative to the physiological pathways through which the reduced flavoproteins are oxidized is far too meager. In reconstructed enzyme systems these flavoproteins, with the exception of the yeast fumarate hydrase, are capable of being oxidized directly by oxygen. It is questionable whether this represents the true physiological mechanism.

| Enzyme | Reaction Catalyzed |
|------------------------------|---|
| <i>d</i> -Amino acid oxidase | Oxidative deamination of the <i>d</i> -amino acids |
| Milk flavoprotein | Oxidation of certain purines, aldehydes and dihydrocoenzyme I |
| Bacterial flavoprotein | Oxidative decarboxylation of pyruvic acid in <i>B. delbrückii</i> |
| Yeast fumarate hydrase | Reduction of fumaric acid by reduced dyestuffs |
| Liver aldehyde oxidase | Oxidation of aldehydes |

Barron²⁹ has advanced objections to the concept of a direct transfer of electrons from the flavoproteins to molecular oxygen, and in support of his viewpoint³¹ quotes evidence indicating that the oxidation of *d*-amino acids and pyruvic acid by bacteria possessing the cytochrome system is completely inhibited by cyanide.^{33, 38} The intermediation of the cytochrome system in the oxidation of these substrates is indicated.

In summarizing the biological activity of the flavoproteins, it may be stated that they function as electron mediators in many biological oxidations by virtue of their ability to undergo a cycle of oxidation and reduction. The isoalloxazine ring is considered to be the functional group in these electroactive oxidation-reduction systems as indicated:

The elucidation of the true nature of the physiological oxidants of many of the flavoproteins remains a fruitful field for investigation. It is apparent that the flavo-

proteins are capable of playing fundamental roles in carbohydrate, protein, and purine metabolism.

Reconstructed enzyme systems have been generally employed to demonstrate the biological activity of the flavoproteins. However, results from *in vivo* studies have substantiated the physiological importance of these compounds. The direct approach has been employed by Urban and Peugnet,²³³ who have been able to demonstrate that cytochrome C and the yellow ferment transfer electrons during individual twitches of a frog muscle. A decreased respiration of rat-liver tissue in riboflavin deficiency has been reported by Groen and Schuyl.¹⁰⁰ Hastings *et al.*,¹⁰⁹ although unable to confirm the results of Groen and Schuyl with regard to the respiration of liver, did observe a significant increase in the respiration of rat diaphragm in riboflavin deficiency. Adams³ reports that the oxygen consumption of the skin of vitamin G-deficient rats is considerably lower than that of normal rats. Kik *et al.*¹¹⁷ were unable to find any significant changes in the digestive efficiency of either the proteolytic or amylolytic enzymes in vitamin G deficiency in the rat, although they did observe a 20 per cent decrease in blood serum phosphatase.

A more clear-cut demonstration of the *in vivo* relationship between riboflavin and respiratory enzymes has been furnished by studies of individual enzyme systems or their components in riboflavin deficiency. Thus, Ochoa and Rossiter¹⁸¹ have reported a decrease in the total riboflavin-adenine dinucleotide content of rat heart and liver in riboflavin avitaminosis. The dinucleotide content was rapidly restored to its normal level by the administration of riboflavin to the deficient rats. The values for the total riboflavin-adenine dinucleotide content of normal rat liver and kidney given by Ochoa and Rossiter¹⁸¹ check well with the figures of Axelrod *et al.*¹⁷ for the riboflavin content of these tissues if it is assumed that all the riboflavin is present as the dinucleotide. The decrease in total riboflavin-adenine dinucleotide content of liver observed by Ochoa and Rossiter is of the same order as that observed by Axelrod *et al.* for the riboflavin decrease in this tissue. A decrease in the riboflavin-adenine dinucleotide content could conceivably affect the concentrations of a number of flavoproteins, and such changes have been observed. Thus, Axelrod *et al.*¹⁷ and Rossiter¹⁹⁶ have shown that a riboflavin deficiency in the rat results in a lowering of the *d*-amino acid oxidase content of various tissues. The former authors have indicated that other members of the vitamin B complex may facilitate the synthesis of this enzyme from riboflavin. The protein constituent of *d*-amino oxidase was apparently not affected in this deficiency.¹⁹⁶ In a similar study, Axelrod and Elvehjem¹³ have reported that the xanthine oxidase activity of rat liver is greatly diminished in riboflavin deficiency. Although no direct evidence was presented to prove the point, the authors are of the opinion that the prosthetic group of this enzyme was diminished in the deficiency.

It has been suggested that succinic dehydrogenase is a flavoprotein.^{190, 191} The final proof that riboflavin enters into the structure of any of the components of the succinoxidase system must await the isolation in pure state of such components. However, the observations of Axelrod *et al.*¹⁸ that the dietary intake of riboflavin affects the succinoxidase content of rat-liver tissue constitute *prima facie* evidence in support of the flavoprotein nature of this enzyme.

Another illustration of the physiological relationship between riboflavin and riboflavin-adenine dinucleotide has been furnished by Klein and Kohn,¹²² who demonstrated the synthesis of riboflavin-adenine dinucleotide from riboflavin by human blood cells both *in vitro* and *in vivo*.

Verzar and his school have been active proponents of the theory that the adrenal cortical hormones are catalysts for the phosphorylation of riboflavin and other members of the vitamin B complex prior to their incorporation as coenzymes of certain enzyme systems. This theory presents many attractive possibilities. However, the

bulk of our present evidence renders such a thesis untenable. An excellent summary of this controversial subject is given by Clark.⁴⁵

Enzymatic Relationships of Other Vitamins

The discussion of the biological activities of thiamine, nicotinic acid and riboflavin largely completes our present knowledge of the interrelationships between vitamins and enzyme systems. However, suggestions have been proposed with regard to the enzymatic activities of the remaining vitamins, and these will be discussed briefly in this section.

Vitamin A. Green⁹⁹ reported that vitamin A deficiency brings about a pronounced fall in the esterase content of blood serum. However, he considered this to be a secondary change. Sure *et al.*²¹⁹ verified Green's results and observed further a decrease in liver esterase and lipase. Sure and DeWitt²²⁰ reported slight decreases in the respiration of cerebrum and heart in vitamin A-deficient rats. No correlation between the severity of symptoms and extent of respiration was noted. Sister M. V. Ruddy¹⁹⁷ has reported that liver tissue of vitamin A-deficient rats has an abnormally low oxygen consumption. Feeding of vitamin A restored the metabolism to normal. Wald²³⁷ has shown that visual purple, an enzyme which catalyzes the process of photoreception, is a conjugated protein with vitamin A as the prosthetic group.

Vitamin D. The high concentration of plasma phosphatase in vitamin D deficiency has long been recognized. This effect may be a secondary one due to the loss of phosphatase from the rachitic bones. Presnell¹⁹³ reported a decrease in the oxygen uptake of skin from rachitic rats.

Vitamin E. Friedman and Mattill⁸⁰ observed an increased oxygen uptake in muscle tissues during vitamin E deficiency.

Pyridoxine. The chemical similarity of pyridoxine to the pyridine nucleotides suggests an enzymatic role for this vitamin. It is significant that, in yeast, pyridoxine occurs in combination with protein.¹³⁸ However, no specific enzymatic function for pyridoxine has yet been determined. The relationship of pyridoxine to fat metabolism has been indicated by Halliday¹⁰⁴ and Engel.⁶² A possible role of pyridoxine in protein metabolism has been suggested by McHenry and Gavin.¹⁶⁹

Biotin. The catalytic function of biotin in fat metabolism is suggested by the observation that the feeding of biotin results in fatty livers characterized by a high content of cholesterol.⁸⁶

A factor essential for the respiration of root nodule bacteria without concomitant growth has been designated as coenzyme R by Allison *et al.*⁶ Coenzyme R is now known to be identical with biotin. Burk *et al.*⁴¹ have demonstrated the ability of biotin to affect both the fermentation and respiration of yeast. A high Meyerhof oxidation quotient was reported for biotin-deficient yeast.

Pantothenic Acid. As is the case with biotin, the role of pantothenic acid in fat metabolism has been indicated by its ability to affect the concentration of liver fat.⁶²

Pratt and Williams¹⁹² have reported the stimulative effect of pantothenic acid upon the respiration of yeast, upon the fermentation by dialyzed maceration juice from yeast, and on the respiration of certain vegetable tissues.

Experiments suggestive of the possible role of pantothenic acid in porphyrin metabolism and in the regulation of water metabolism have been reported.^{75, 164, 44}

***p*-Aminobenzoic Acid.** The chromotrichial activity of *p*-aminobenzoic acid^{7, 161} and the antagonism between hydroquinone and *p*-aminobenzoic acid with respect to graying of hair, have indicated a possible relationship between the metabolism of phenolic substances and *p*-aminobenzoic acid. The observations that it has a pronounced influence on tyrosinase activity²⁵⁸ and is capable of modifying enzymatic melanin formation¹⁶² are in accord with such a relationship. The experiments of Lipmann¹⁴⁸ may have some bearing on this question.

Ascorbic Acid. The relatively high concentrations of ascorbic acid in living tissue and its intense reducing action early suggested the theory that this compound serves primarily as a hydrogen transport agent. Numerous attempts have been made to demonstrate the "carrier" function of ascorbic acid in animal tissues with but little success. King¹¹⁹ concludes "that the evidence is more negative than positive in regard to the postulated respiratory role of ascorbic acid in animal tissues." Objections to the "carrier" role of ascorbic acid have also been raised by Barron.⁸⁰ Stronger evidence is available in support of the theory that ascorbic acid serves as a respiratory catalyst in certain plants.¹¹⁹ However, the application of the more recent information relative to the biocatalysts necessary for the complete transfer of hydrogen (*i.e.*, flavoproteins) may help considerably toward closing the gaps in our present knowledge of the physiological function of ascorbic acid. It should also be borne in mind that the combination of acidity and reducing action which characterize the chemical behavior of ascorbic acid may determine its role as that of a regulating and protective agent toward other enzyme systems. The assumption of a protective action for ascorbic acid may serve to rationalize the observations of Harrer and King¹⁰⁶ that the concentrations of liver esterase and succinic dehydrogenase are diminished in scurvy. The inhibiting or activating effect of ascorbic acid on such enzymes as cathepsin, papain, amylase, arginase, catalase, urease, tyrosinase and nuclease may conceivably be attributed to the non-specific acidity and reducing capacity of ascorbic acid.¹¹⁸

Other functions for ascorbic acid have been proposed. Lemberg and associates¹⁴² have demonstrated the part played by ascorbic acid in catalyzing the formation of bile pigments from oxyhemoglobin. Ecker and co-workers^{57, 58} have shown a definite correlation between the complement titer of both guinea pig and human serum and the ascorbic acid content of such sera. Ascorbic acid is believed to function in maintaining the complement in a reduced, active state.

Sealock and co-workers²⁰⁰ have proposed a functional role of ascorbic acid in the metabolism of phenylalanine and tyrosine.

Summary

A large body of evidence has been accumulated in support of the thesis that the biological activities of thiamine, nicotinic acid and riboflavin are due to their abilities to serve as components of enzymatic systems. The experimental proof has been derived from both *in vivo* and *in vitro* researches. A similar relationship has been postulated to explain the physiological role of other vitamins, but, in these cases, clear-cut experimental evidence for such functions has not been forthcoming.

The knowledge that the functional role of the vitamins is closely correlated with their enzymatic relationships is but the first step toward the complete elucidation of the biological action of vitamins. Some of the questions which still remain unanswered are included in the following:

(1) What individual metabolic reactions are affected in a given vitamin deficiency? Thus, although it is recognized that the cocarboxylase, the pyridine nucleotide and the flavoprotein concentrations of certain tissues are materially affected in some vitamin deficiencies, the information relative to the derangements in the specific metabolic reactions catalyzed by these enzyme systems is quite unsatisfactory. Answers to this question have been sought for most vigorously in the case of thiamine deficiency. The first attempts in this direction are being made in studies of riboflavin and nicotinic acid deficiencies.

(2) How are the over-all metabolic reactions of the organism affected by changes in the activities of their component parts? An answer to this question will involve the *in vivo* corroboration of the *in vitro* studies carried out with reconstructed enzyme systems. To take a specific example, it remains to be demonstrated that the decrease in the xanthine oxidase system, which has been observed in riboflavin

deficiency, in any way affects the ability of the animal to metabolize purines. A similar situation exists in other vitamin deficiencies where studies on carbohydrate, fat and protein metabolism have not been exhaustively pursued.

(3) Is there any positive correlation between the extent of the metabolic changes and the severity of the deficiency syndrome? Attempts to answer this question will promote the establishment of a more quantitative relationship between the enzymatic derangements and the observed pathological changes. Studies of this type may also be of value in any attempted correlation between a specific pathological event and a disturbance in a given enzymatic system.

Minerals and Vitamins in Applied Nutrition

LELA E. BOOHER

General Mills, Inc., Minneapolis, Minn.

Man's dependence upon an array of minerals and vitamins in his food supply becomes more intelligible in the light of his evolution in, and from, a material environment wherein a wide range of inorganic matter has unfailingly persisted and wherein widespread synthesis of vitamins had previously developed in the plant kingdom. The preeminence often accorded the proteins as fundamental constituents of all living matter should not detract attention from the fact that the vitamins are indispensable for certain structural developments and functional processes associated with life, or from the fact that the chemical reactions which characterize living matter can proceed only in aqueous solutions of appropriate kinds and concentrations of electrolytes. The minerals, the vitamins, and the hormones regulate or control most, if not all, the vital cellular activities within man's body.

MINERALS IN APPLIED NUTRITION

The elementary composition of the human body has frequently been compared with that of the material environment from which it evolved, namely, the earth's crust, the atmosphere, and the sea. This comparison has revealed both similarities and dissimilarities of composition without having revealed any direct chain of continuity between the two. However, a distinct continuity between the material composition of sea water and that of the body fluids of man was suggested by Bunge in 1889 and by Quinton in 1897, a thesis which has been further developed by Macallum.¹ Without doubt, life began in the sea and in the course of evolutionary development some forms made the advance into fresh water or onto land, there to continue and modify in new environments their progression of evolutionary developments. Macallum develops the concept that whereas proteins are universal constituents of living things, they are not uniform in composition in the wide range of cellular life, and so cannot be regarded as chemical endowments from a remote past. On the other hand, certain inorganic constituents always associated with living matter are present in living cells and their media in so nearly constant proportions (although not in the same proportions in the cells as in their media) that they would

appear to be of paleogenetic character. The inorganic constituents presumed to be in this category include chloride, sulfate, phosphate, carbonate, sodium, potassium, calcium, and magnesium. Macallum advances the view that "the blood plasma of vertebrates and invertebrates with a closed circulatory system is, in its inorganic salts, but a reproduction of the sea water of the remote geological period in which the prototypic representatives of such animal forms first made their appearance." The tissues of ancient oceanic forms of life, it is suggested, had throughout a long period accommodated themselves to the composition of the sea water of that period, so that when, in the course of evolutionary processes, the circulatory system became closed, the composition of the sea water of that time was, with slight modification, reproduced in the vascular fluid and transmitted to descendent forms living in similar or different habitats. Macallum presents several types of data and deduces arguments and reflections in support of this view of the paleogenetic character of certain inorganic constituents of living cells and their media, the original exposition of which readers of this chapter may find of unusual interest.

The vascular fluid is separated from other body fluids by membranes which exhibit varying and highly selective permeabilities. There exist very definite physicochemical equilibria between the constituents of the vascular fluid and those of other body fluids. An inorganic composition of vascular fluid which is fixed within narrow physiologic limits, therefore, presupposes inorganic compositions of other body fluids which likewise vary only within respective narrow limits. Substantial and sustained departures from these narrowly circumscribed compositions of the body fluids are associated with morbid states of the body.

The materials required for the building and maintenance of the inorganic structures of the body are derived from food and water. Against insufficiencies of supplies of essential inorganic nutrients the body can make only limited compensatory adjustments. Excess supplies of one or more inorganic nutrients can ordinarily be disposed of by the body through one or more of the specialized channels of excretion. Intelligent application of the science of nutrition necessitates a thorough understanding of the fundamental principles of physiology and a knowledge of nutritive requirements in terms of common food items.

Sodium, Potassium and Chlorine. A loss of about 10 per cent of the total body water results in impairment of physical well-being, and a loss of about 20 per cent results in death. However, it is not the loss of body weight *per se* but rather the alteration in the concentrations of electrolytes in the body fluids which is the prime factor involved in these adverse phenomena.

On a fat-free basis, the water content of the body shows successive changes with age. Starting in early embryonic life there is a progressive decrease in the proportion of body water throughout the period of growth. From the period of attainment of maturity through middle life, the water content of the body remains almost stationary, but increases, at least in the muscle mass, in old age. The muscle mass of the infant constitutes about 25 per cent of the body weight, that of the adult usually somewhat over 40 per cent.

The changes in water content of the body with age are more readily discerned in the light of the successive changes which take place in the proportion of intercellular to intracellular fluid in the soft tissues, particularly in the muscles. Examples of the analytical procedures and calculations employed in estimating the relative water contents of the intercellular and intracellular fluids of muscle, together with references to previous work on this subject, can be found in a recent report of Lowry and Hastings.² The boundaries separating the intercellular fluid from the intracellular fluids are ordinarily considered to be impervious to inorganic cations. The osmotic pressure of the intercellular fluid is due principally to sodium and chloride ions, that of the intracellular fluids principally to potassium and phosphatic ions. The concentrations of the respective major cations and anions in the two fluids are

normally almost constant throughout life except for transitory changes which occur during periods of normal physiologic adjustment. Changes in the sodium, chlorine, potassium and phosphorus contents of the tissue, therefore, reflect definite changes in the proportions of the intercellular and intracellular fluids. During growth, expansion of the muscle mass is accompanied by corresponding decrease in the volume of intercellular or interstitial fluid, which, because it has a lower content of solids than the muscle fibers which it bathes, results in a lower percentage of total tissue water. With attainment of full development and until old age, the distribution of body water remains essentially unchanged. With the advance of old age, the size of the muscles usually diminishes, as a result of either atrophy of disuse or actual loss of muscle fiber, and is attended by an increase in the ratio of interstitial to intracellular fluid.³ The suggestion is made that the somewhat lowered basal metabolic rate so frequently observed in aged individuals may be due to this increase in volume of interstitial fluid relative to the mass of active cytoplasm. The gross body weight or body surface in such case would, therefore, be associated with a smaller proportion of metabolically active tissue than in the case of a middle-aged adult of identical body weight or body surface. These same alterations in the proportions of interstitial and intracellular fluids in the aged may also not be without functional consequence on muscular capacity and efficiency, since the greater distance between capillaries and muscle fibers would diminish the rate of interchange of metabolites.

McCay and Crowell⁴ have reported that animals maintained on a diet adequate except for calorie intake are, by comparison with animals on adequate diets without restriction of calories, especially long-lived and youthful into the period of advanced age. The skeletal muscles of animals retarded in growth through limitation of calorie intake were shown⁵ to possess the muscle fiber composition and the relatively higher proportions of interstitial fluid characteristic of chronologically younger animals. It is apparent then that histochemical studies of tissues may reveal very interesting phenomena which remain puzzles when insight is limited to grosser studies of tissue composition.

Gamble⁶ has estimated that the body water of an adult is distributed among vascular fluid, interstitial fluid, and intracellular fluid at roughly 5, 15, and 50 per cent, respectively, of the total body weight.

From studies of isolated living tissues, including blood (circulating tissue), it can be shown that the selective permeability of the boundaries between cells and intercellular fluids is the equivalent of semi-permeable membranes and that the ratio of concentration of permeating ions within, to the concentration without the cells conforms to the theory of Donnan equilibria. Studies of isolated tissues furnish abundant evidence that the boundaries between cells and the fluid surrounding them are impervious to cations. For the most part, these boundaries would seem to manifest the same characteristics in the intact tissues of the body, but there are obvious exceptions. During starvation, or following ingestion of acid, potassium ions do cross these boundaries, since both sodium and potassium ions may then be found in the urine in similar amounts. Likewise, potassium ions must cross in the other direction, else muscle fibers could not grow nor could the loss of potassium resulting from exercise be restored by ingestion of potassium.

The osmotic pressure relationships of the tissue fluids in which the inorganic ions play the leading role are interestingly manifested under various abnormal circumstances. The consumption of diets deficient in protein will, if sufficiently prolonged, lead to edema of the tissues. Some investigators insist that edema will not develop under these circumstances unless there is simultaneously an adequate or unrestricted intake of water, a condition which is not likely to be lacking in the realm of human experience.

As a result of the low protein intake, the concentration of proteins in the blood

plasma is reduced, and this is accompanied by progressive accumulation of interstitial fluid of normal osmotic pressure. Edema resulting from such diets was observed endemically in Central Europe during World War I and was commonly referred to as "war edema," "famine edema," or "hunger edema." The diets causing this condition were poor in many nutritional respects. However, attention is focused upon the low-protein aspect of the diets, because reduction of protein concentrations of the blood plasma of animals by mechanical means and the low-protein content of the blood plasma common in nephrosis, accompanied by marked albuminuria, are also associated with edema. The explanation of this phenomenon rests on the basis that reduction of the proteins of the plasma lowers the osmotic pressure of the colloids in the capillaries to a degree incompatible with the normal return of the transudates to the blood vessels. Fluid transudate, therefore, accumulates in the tissues. War edema, or edema caused by mechanical depletion of plasma proteins, can be alleviated by liberal feeding of protein.

The excessive accumulation of fluid in the tissues, commonly called edema, may be any one of three types, namely, hypertonic, hypotonic, or isotonic, depending upon whether the osmotic pressure of the tissue fluids has been increased, decreased, or unaltered. Any factor which changes the osmolar concentration in one compartment of the body fluids causes adjustments to take place in the others, since osmotic pressure is equalized throughout the body.

It is commonly known that if sea-water, which corresponds to about a 3 per cent NaCl solution, or other water of high NaCl content, is used as human drinking water, death will eventually ensue. The high ingestion of NaCl relative to the volume of water leads to diminished secretion of urine and increased osmotic pressure of the body fluids (hypertonic edema) beyond the limits of physiologic tolerance. The converse of this situation is exemplified by copious ingestion of ordinary drinking water following profuse sweating which has been attended with large salt as well as large water loss through the skin. The result is water intoxication (hypotonic edema of the tissues), or in more popular terms "heat cramps" or "miner's cramps." Persons who are subjected to environments which induce copious sweating are advised to replenish their salt and water losses by drinking water to which an appropriate amount of salt has been added, or to ingest salt tablets along with ordinary drinking water. In intensely warm environments, the body does gradually make some degree of adjustment to restrict NaCl losses. This is accomplished by secretion of sweat of lower NaCl concentration. In an environment of high temperature, the individual unaccustomed to very warm environments, therefore, is the more likely to suffer from heat cramps, if the drinking water is not supplemented with ingestion of salt.

A high intake of NaCl accompanied by unrestricted intake of water, such as man occasionally indulges in through consumption of highly salted foods, may also result in temporary edema. Similar results have been observed following consumption of fairly large quantities of isotonic salt solution (0.9 per cent sodium chloride solution). In the first instance, if the water intake has been low, the ready absorption of the NaCl into the vascular system initiates a desire for water which is usually very promptly gratified. In both cases, absorbed NaCl, along with water, rapidly leaves the blood stream and increases the volume of interstitial fluids (isotonic edema). Once dissipated, it is withdrawn from the tissues and eliminated only gradually. By contrast, ingested KCl is normally followed by its very prompt excretion by the kidneys. The interstitial fluid is incapable of storing KCl and the body cells, unless depleted of potassium previously, are impervious to potassium ions. Hence the concentration of KCl in the blood plasma is rapidly built up, with consequent rapid excretion of KCl by the kidneys. As this course of events suggests, potassium salts act as diuretics, and large doses are not well tolerated by the body.

Consumption of excessive quantities of ordinary drinking water by persons other-

wise following their customary habits of living can result in adverse effects. The excessive intake of water causes NaCl to be swept out of the body, and water, if taken in faster than it is eliminated, accumulates in the tissues (as hypotonic fluid), and such symptoms as headache, weakness, nausea, or even more adverse effects may result. These several illustrations serve to show the very distinct and essential function of the kidneys in maintaining physiologic balance among the inorganic constituents of the tissues within the narrow limits compatible with life.

It is obvious from these few illustrations, to which many more could be added, that the osmotic equilibria of and water distribution in the tissues are *largely* controlled by sodium, potassium, chloride, and phosphatic ions in consequence of their being the major ions in the body fluids.

Carnivorous animals, because of their relatively intense muscular activity, require diets rich in potassium. These are provided them by flesh foods, while their lesser need for sodium is provided chiefly by consumption of the body fluids of their prey. Herbivora, in consuming plant food, obtain a diet much richer in potassium than in sodium, but "salt licks" are coveted by them to such extent that, in the wild state, they will risk capture and loss of life to satisfy their desire for salt (NaCl). Man, as a consumer of a combination of foods from plant and animal sources, supplements his diet with relatively large intakes of NaCl, probably to a far greater degree than any normal need could possibly impose. The exercise of individual preference in the amount of salt consumed by man has, so far as we know, created no health hazards; it does promote good digestion and enjoyment of food and thus contributes to the utilization of certain important foods which, were they not seasoned with NaCl, might be refused. The average American adult consumes from 10 to 15 grams of NaCl per day, in addition to ingestion of such quantities of sodium and chlorine as exist naturally in the foods consumed. The average diet also carries an abundance of potassium, a common element in normal food items.

Life was adapted from the first to an environment where abundance of sodium, chlorine, and potassium enabled evolutionary forces to utilize these elements in ionic forms to stabilize fundamental life processes. By reason of the inherent necessity of retaining a composition of body fluids closely related to that of a sea-water of a remote past, natural selection, which rejects every false try and unsuccessful experiment, must have played a large role in the preservation of those non-aquatic forms of animal life which succeeded in establishing satisfaction of their primary needs for these elements. What the whole human race has already instinctively and justifiably applied as an established food habit is a problem of applied nutrition already solved.

Magnesium, Calcium and Phosphorus. Magnesium is found almost universally in living tissue. It is a normal constituent of all animal tissues. In plants, it forms complex ions with protein;⁷ it is a fundamental constituent of chlorophyll; it is associated with many weak organic acids such as malic, tartaric, citric and oxalic in plant juices; and is widely distributed in the plant kingdom, especially in the pericarp of cereal grains as a magnesium-calcium salt of inositol phosphoric acid (phytin, so-called).

Magnesium is a constant constituent of bone (about 0.03 per cent of the bone ash), and may exist there as a phosphate, a mixture of phosphate and carbonate, or possibly as a complex salt with calcium phosphate. Whether the magnesium enters into the structural pattern of the deposited mineral of bone, or exists there as an admixture, is not known. Magnesium ions are definitely known to act as catalytic agents for certain enzymatic reactions associated with muscle metabolism, specifically energy transformations in the tissues.

Although they are closely related chemically to calcium, one of the most interesting properties of magnesium ions in living tissue is their counterpoise effect, or physiologic antagonism to calcium ions. McCollum and his associates^{8,9} have de-

scribed the spectacular syndrome of magnesium deficiency in animals which seemingly is related to an imbalance of magnesium and calcium ions in the body tissues. The adverse effects of diets deficient in magnesium are intensified by liberal ingestion of calcium, and *vice versa*. The presence of excessive quantities of magnesium in the tissues, which can be induced by injections of magnesium salts in suitable amounts, will result in anesthesia in man. In animals it has been shown¹⁰ that, depending upon the quantity of magnesium salts injected, anesthesia or even death may ensue. The anesthesia induced in the two species by injection of magnesium salts can be offset by injection of soluble calcium salts. These interrelations of magnesium and calcium ions in living tissues all appear to be related to the irritability of the tissues.

The normal irritability of muscle is controlled and maintained by an interrelation of inorganic ions, including potassium, sodium, calcium, magnesium and hydrogen ions, in the extracellular body fluids. This relationship has been expressed¹¹ thus:

$$\text{Irritability} \propto \frac{[\text{Na}^+] + [\text{K}^+]}{[\text{Ca}^{++}] + [\text{Mg}^{++}] + [\text{H}^+]}$$

Hence sufficient alteration in the concentration of any one of these interrelated inorganic ions would impose change upon the irritability of muscle. A high concentration of magnesium ions would decrease muscle irritability, and a low concentration would increase it. These properties of magnesium have been demonstrated experimentally. The complete story of the interrelations of inorganic ions in the control of muscle irritability has not yet been revealed, as one may deduce from consideration of the above pseudo-mathematical expression and the results observed on muscle irritability by imposing a high concentration of calcium ions upon a high concentration of magnesium ions.

Hyperirritability of the neuromuscular system, resulting in tetany characterized by laryngeal spasm, spasm of the muscles of the wrists and ankles, and generalized convulsions, has often been observed by clinicians in such conditions as hypoparathyroidism, rickets, and severe osteomalacia, which are the result of low concentrations of calcium ions in the extracellular fluids, a condition which is revealed in a low calcium concentration in the blood serum. Factors resulting in sufficiently high pH values of the extracellular body fluids (also revealed in high pH values of the blood plasma) can also induce tetany. Some of the adverse affects of ingestion of large amounts of NaCl or KCl, particularly when accompanied by highly restricted water intake, are logically to be expected in view of the ionic interrelationships shown above.

Magnesium salts, when orally ingested, exhibit cathartic and diuretic effects. Following administration of hypertonic solutions of MgSO_4 (Epsom salt), for example, water is drawn into the intestine, thus reducing the degree of hypertonicity of the salt solution. Some of the magnesium salt will be absorbed as it moves down the intestinal tract; but as neither magnesium nor sulfate is readily absorbed, catharsis is manifested. In general, the readiness or efficiency of absorption of inorganic ions from the intestines follows the order of the Hofmeister series. Magnesium citrate has a less dehydrating effect than MgSO_4 and therefore exhibits milder cathartic effects.

Sherman¹² estimates from surveys of 150 freely chosen dietaries that the average American diet contains 0.34 gram (range 0.17 to 0.53 gram) of magnesium per 3000-calorie intake of ordinary foods. A deficiency of magnesium in the diet, while theoretically possible, is not of practical concern in applied nutrition because of the widespread occurrence of magnesium in common foods and the apparent adequacy of ordinary diets to supply physiologic needs. Balance experiments show wide varia-

tions in the retention of magnesium, and the physiologic requirements cannot be said to have a satisfactory basis to date.

Over 98 per cent of all the calcium in the body is found in the skeleton and teeth, but the small amount in the soft tissues is, nevertheless, of great physiologic importance. The phosphorus content of the bones and teeth accounts for about 80 per cent, that of the muscles for about 10 per cent and that of nervous tissue for about 1 per cent of the total body phosphorus. The phosphorus in the soft tissues occurs in a wide variety of forms, including phosphoproteins and phospholipids, as well as phosphate in ionic form and in combination with numerous organic substances.

In bone, calcium and phosphorus are laid down in an organic matrix, along with a certain proportion of magnesium. Bone also contains smaller proportions of other inorganic elements, notably sodium, potassium, and chlorine. The arrangement and composition of the inorganic matter of bone is apparently that of the apatite minerals, corresponding to $n\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCO}_3$, in which n is not less than 2 nor greater than 3. This structure is very similar to the apatite mineral dahllite.¹³ As one would expect, therefore, the ratio of calcium to phosphorus in bone ash is practically invariant, regardless of the degree of mineralization of bone. However, in elderly persons the bones do appear to change somewhat in ash composition. The bones of aged persons usually become somewhat brittle and are found to contain larger proportions of CaCO_3 than do those of younger persons. This situation is commonly reflected by an increased ratio of bicarbonate to phosphate in the plasma or serum as well.

Fluorine, when deposited in bone, replaces part of the carbonate normally present. Sodium and chlorine are present in the body fluid of bone. As the bones become mineralized to greater extents, their water, sodium, and chlorine contents diminish. Under special circumstances, radium, lead, barium, beryllium, and strontium may also occur in bone, depending largely on the quantities ingested.

Bones are not "fixed" body structures. They are vascular organs and can yield or deposit mineral substance as the occasion demands. Their net-work of bone trabeculae has been shown¹⁴ to increase and decrease quite readily. However, this situation may be altered in aged individuals whose bone trabeculae have been greatly thinned or may have disappeared altogether or been replaced by cysts.¹⁵ In such cases it would seem that mineral deposits lost from the trabeculae might not be capable of restoration, and it is inconceivable that it could be so if the matrix of the trabeculae was disorganized or had disappeared. The teeth, likewise, are not immune to changes in mineral composition, since radium, which presumably can replace some of the calcium in tooth structures, has been found in the dentine of persons exposed to radium poisoning. It is generally conceded, however, that once the teeth have been fully developed, they alter their structures much more slowly than the skeleton. For the promotion of structurally strong teeth, therefore, proper nutrition during their formative period would seem to be unusually important, and this period begins before birth. Calcium, phosphorus, and vitamins A, D, and C have been pointed out as dietary factors particularly important in building good tooth structures.

The difficulties of assessing the absolute and relative amounts of phosphorus in different forms in various parts of the body are very great in view of the fact that phosphorus is present in so many types of compounds, often very closely related chemically and some of them quite labile. The oxidation-reduction reactions in muscle, and the chemistry of muscle contraction, for which glucose and its derivatives supply the energy, proceed by a series of intermediate reactions wherein phosphorylations and dephosphorylations of the metabolites are essential parts of the processes. Recent contributions to our knowledge of muscle physiology form one of the brilliant chapters in biological science.* The use of radioactive phosphorus in

* See paper by O. Meyerhof in this volume. J. A.

compounds introduced into the body, and subsequent study of its transfer to various phosphorus-containing compounds, has also opened up a new field of research in phosphorus metabolism.

Nucleoproteins occur in every cell and cell nucleus in the body. Inorganic phosphate is a constituent of both intracellular fluids (excepting perhaps in the red blood cells) and intercellular fluids and of the body excretions and many of the body secretions as well.

In the discussion of the vitamins, riboflavin, nicotinic acid and thiamine, phosphorus will be seen to form an essential part of several coenzymes. The importance of phosphorus in the nutrition of the body can hardly be over-emphasized, for it is associated with both numerous and intricate reactions of life processes.

Rapid mineralization of the skeleton normally begins two or three months before birth, and under favorable circumstances continues at increasingly rapid rates until about the age of puberty, after which the rate of mineral deposit gradually falls off until, with attainment of full development, the body's needs for calcium and phosphorus are limited to maintenance requirements.

Numerous investigations have been conducted in an attempt to define the calcium and phosphorus requirements of persons of different ages. Even among supposedly normal persons, the needs of any age group show wide variations from individual to individual. It is, therefore, possible to define so-called requirements only in terms of rough approximations. In addition to inherent differences among individuals on the same dietary regimen, many other factors make for wide variations in average calcium and phosphorus requirements of persons in different age groups.

As mentioned earlier, the readiness with which inorganic ions are absorbed from the intestinal tract follows in general the order of the Hofmeister series. Calcium and phosphorus, therefore, are by their very nature less readily absorbed than are, for example, sodium, potassium, and chlorine. Many dietary factors and physiologic conditions affect the degree of utilization of calcium or phosphorus, or both. The presence of oxalates or large amounts of fatty acids in the intestinal tract causes precipitation of insoluble calcium salts and thus renders calcium unavailable for absorption. Large amounts of indigestible residue in the food are also believed to be unfavorable for the absorption of calcium and phosphorus. An excess of calcium or of phosphorus in the food causes corresponding excretions of these elements through the bowel. The presence of vitamins D and C in the diet reacts favorably toward the utilization of calcium and phosphorus. The degree to which the body stores approach being filled with calcium and phosphorus will affect the degree of retention of these elements. Abnormal physiologic conditions, such as acidosis, endocrine imbalance, and diarrhea may impose unusual restrictions on the use of dietary calcium and phosphorus for nutritional purposes, and may in some cases result in removal of large quantities of these inorganic nutrients from skeletal reserves.

It is apparent that the physiologic needs for calcium and phosphorus are not easily established even for normal individuals. In a recent review of the subject, Macy¹⁶ summarizes the situation thus: "Neither the most satisfactory level of calcium intake nor the optimal retention of calcium at any physiologic age or stage of man's development is known."

It is, however, quite obvious that the infant or child requires a liberal intake of both calcium and phosphorus because normal development involves an increase not only in the amount, but also in the percentages of body calcium and phosphorus during growth. Adequate amounts of vitamin D are essential for their utilization. The calcium and phosphorus in milk are exceptionally well utilized and are present in milk in a ratio ($\text{Ca/P} = 1.3$) that corresponds roughly to the ratio in which they are retained by normally developing infants and children. A lower ratio of Ca/P in the diet is satisfactory for the average adult whose needs for calcium, once the skeleton has become fully developed, are less than for phosphorus, which is required

not only for skeletal maintenance but also in much larger quantities than calcium for servicing the needs of large masses of muscle and other soft tissues wherein phosphates play a highly important role.

Most of the efforts directed toward estimating calcium and phosphorus needs of the human body have been based on studies of the relationships between the amounts of these ingested and excreted by groups of individuals in various age groups. Very few studies have been made on the calcium or phosphorus requirements of elderly persons. Obviously excretion of a smaller amount of an inorganic nutrient than that ingested indicates bodily retention of the nutrient; a quantitative balance between the two indicates lack of retention, but no bodily loss of the nutrient; while an excretion exceeding the intake indicates a negative balance or loss of the inorganic nutrient from quantities previously acquired by the body.

The average daily requirement of calcium based on 97 experiments on 24 adults and calculated by arithmetic proportions to a uniform basis of a 70-kg adult was reported by Sherman¹⁷ to be 0.45 g (range 0.27 to 0.82 g). Similarly, on the basis of 95 experiments on 21 adults, Sherman¹⁸ has reported the average phosphorus requirement for 70-kg adults to be 0.88 g, with a range of values from 0.52 to 1.20 g per day. Sherman has until recently recommended an excess of 50 per cent over these average minimal requirements for calcium and phosphorus as a daily allowance, but he now considers that twice the minimal requirement is a better standard in the case of calcium. This increase in recommended daily allowance of calcium is based upon the favorable effects observed in physiologic performance of animals fed on diets providing higher levels of calcium than had previously been considered entirely adequate. According to his interpretation of the observations made by himself and his co-workers, and in the light of his interpretation of researches recorded in the literature, he recommends about 0.9 g of calcium and 1.3 g of phosphorus per 70-kg adult per day as a general guide for planning food selections which will provide good allowances of these nutrients.

Leitch,¹⁹ as a result of critical evaluation of 400 calcium balance studies on women, as recorded in the literature, places the adult maintenance requirement for calcium at 0.55 g per day. She states that there is no adequate basis to show what the extra daily allowance of calcium for adults ought to be. The statistical method of interpretation of the available data as presented in the publications of Leitch is particularly worthy of mention, since it represents a critical approach and a logical means of bringing the numerous reports in the literature to bear on the objective of defining the adult maintenance requirements for calcium.

It is certainly true beyond any doubt that the average adult in this country ingests less than 50 per cent excess of calcium over the reputed average daily maintenance requirements, not to mention 100 per cent excess. It might be expected then that evidences of widespread deficiency of calcium among adults of this country would be observed. Actually, medical reports on such a state of affairs are decidedly lacking. Whether this is because such a state of affairs does not exist, or because the means of detecting less than very gross states of calcium deficiency are inadequate, is a question which at present has no answer.

Many of the calcium balance studies on adults have been of very short duration. The previous nutritional history as regards the calcium intake of the subjects studied has also been passed over or not recorded in the published reports in most cases. If a subject had a previous history of low calcium intake shortly before initiation of a short-term study of calcium balance, the results would not be a measure of maintenance requirement but a measure of this plus what was used to replenish some of the previous losses. In view of the large variations (of the order of 400 per cent) recorded for the daily maintenance requirements of adults, it is obvious that a recommended daily allowance of the order of 0.9 g per day would represent, for a considerable proportion of the subjects thus far studied, a several-fold excess over that

amount which would prevent any calcium loss from the body. It has been generally recognized that substantial excesses of calcium in the diet may unfavorably influence the assimilation of iron, and recent research reports²⁰ add additional evidence in support of this thesis. On a physiologic basis, it would be difficult to understand how any benefits *specifically* referable to calcium could be presumed to derive from larger intakes of calcium by adults than would support a balance between intake and excretion of this nutrient.

As a practical guide, it can be stated that when children receive about 1½ pints to a quart of milk daily, and average adults a pint of milk daily, with each group consuming such kinds and quantities of other common foods as are required to provide a well-balanced diet, the calcium and phosphorus needs of the body are satisfactorily met.

Infants fed on breast milk or on a suitable cow's milk formula in accordance with the best accepted practices, have no need for additional amounts of calcium or phosphorus. The breast-fed infant utilizes larger proportions of the calcium and phosphorus ingested than does the infant fed on cow's milk, but the total intake of calcium and phosphorus by the latter is such that the skeleton is the more rapidly mineralized. This does not imply that the infant fed on cow's milk is necessarily better-nourished, for there are many other differences between breast milk and modified cow's milk formula in which breast milk is obviously superior, for example, curd-type and ascorbic acid value.

The daily dietary allowances for calcium and phosphorus for persons of different ages and sexes, as well as the allowances for other nutrients, as recommended by the Food and Nutrition Board of the National Research Council,²¹ should be consulted by those who are especially interested in contemporary thought along these lines. As stated in the introduction to this report, the term "Recommended Allowances" rather than "Standards" was adopted by the committee to avoid any implication of finality, thus indicating that the recommendations are offered tentatively and until such time as more exact data can be obtained. This document represents the combined judgment of many nutrition authorities and, as such, is a contribution to be highly valued. It is to be hoped that it will be a challenge to research workers in many fields to subject present knowledge of nutritive requirements to closer scrutiny and to devote renewed research effort to the problem of improving our knowledge of the nutritive requirements of man.

The special dietary needs of women during reproductive periods is a highly important subject in the field of applied nutrition, which it is not possible to elaborate on here. A proper application of nutrition during these periods necessitates adequate provision of the kinds and amounts of foods which will meet the ordinary nutritive demands of the maternal tissues and at the same time provide adequate structural materials for building a completely new organism and supplying it with the nutritive essentials required. Recommended daily allowances of specific nutrients for women during reproductive periods are included in the summary prepared by the Food and Nutrition Board.²¹

It might not be amiss to mention here that a large part of the science of nutrition as of today is based upon animal experimentation. Some of this new knowledge is directly applicable to the nutrition of man; some of it is not. In addition, it is well to keep in mind that the overall objective with regard to the feeding of domestic animals used by man as converters of plant food, is not the same objective as desired in the nutrition of man. It is generally accredited that high rates of growth and development, body size, and body weight in practices of animal husbandry are indications of dietary superiority, but the objective in animal husbandry is one of sheer exploitation with but a single purpose in view. We may well question whether the height and dimensions of man are reliable measures of his nutritive status. Certainly we have no evidence at hand to indicate that a relatively small man is, in any fundamentally important aspect of life, inferior to the six-foot tall, athletic type. Further-

more, there are indications that a certain degree of abstemiousness with regard to food consumption is highly favorable to longevity;⁴ certainly mortality statistics of the life insurance companies bear witness that over-weight in the human race is distinctly unfavorable to a long life span. We are now in an era where great enthusiasm attaches to the protective food elements and their possibilities in promoting the welfare of mankind. There seems almost to be a general impression that "the more vitamins and minerals you consume, the better," an impression which has no scientific basis. This over-enthusiasm is already beginning to be subject to the scrutiny of more thorough-going researches, and a tone of more moderation with regard to vitamin and mineral consumption is almost certain to be not too far off. Nutrition is a young, a very young science, and it has opened up so many fields for the prevention of obvious malnutrition that the temptation, fanned by a wave of popular sentiment, to extrapolate beyond reasonable limits will, perhaps, only wear itself out as time and further researches bring more substantial evidence and more seasoned judgment to take its place.

Iron and Copper. Iron exists in largest functioning quantities in the body as a constituent of blood and muscle hemoglobin. Iron is also a constituent of the tissue cytochromes (concerned with certain steps in the process of hydrogen transport from tissue metabolites to molecular oxygen), and of the chromatin material of all cell nuclei.

Hemoglobin is synthesized by the body, a process in which traces of copper acting in the capacity of catalytic agents are required. Aside from this function, little is known of the physiologic need for copper, although it is found in traces to be quite widespread in the body tissues. Anemia in adults, which results from dietary deficiency of iron, seemingly responds to administration of iron without supplementary feeding of copper. This may be due to the fact that the iron salts used in the treatment of the anemia are sufficiently contaminated with copper or that copper is adequately provided for by ordinary diets. In animals, an anemia requiring supplemental copper in addition to iron has been produced as a result of feeding a diet composed exclusively of cow's milk,²² so it is possible that an analogous situation could develop in infants too long restricted to a diet composed exclusively of this same food.

Iron, unlike the other inorganic nutrients discussed here, and also unlike the vitamins, is not used up nor excreted in appreciable amounts from the body once it has been absorbed. Iron is conserved by the body with great tenacity and is used over and over again. Brownish-yellow masses, believed to be a colloidal form of ferric hydroxide, so-called hemosiderin, have been noted especially in the liver, spleen, and kidneys, and are supposedly the endogenous sources of iron which the body conserves for reuse.

The infant at birth possesses a reserve supply of iron. Until rather recently, it was supposed that this reserve iron was stored in the livers of new born infants.²³ It is now believed that this reserve source of iron exists in the blood which in the newborn carries around 20 mg of hemoglobin per 100 ml in comparison with around 15 mg of hemoglobin per 100 ml of blood in adult men. Adult women usually have about 10 per cent less hemoglobin per 100 ml of blood than adult men. However, women also have correspondingly fewer red blood cells, so that the concentration of hemoglobin in the red blood cells of the two sexes is approximately the same.

Some concern has developed in recent years over the fact that quite a number of otherwise normal persons have low values for blood hemoglobin, in terms of standards established as norms some years ago. However, it would seem that this situation might be due to other causes than a dietary deficiency of iron, and might even exist in individuals possessing large stores of iron in their bodies. The body seems to regulate its hemoglobin formation to meet its needs for this oxygen-carrying compound. It is well known that the hemoglobin level and red blood cell count of the blood are increased as a natural physiologic consequence of living at a high altitude.

The body compensates for the lower oxygen content of the atmosphere by increasing its facilities for greater aeration. Thus there is a physiologic adjustment in response to need under changed conditions. The mechanical age in which we live has imposed a life of considerably lessened physical activity on many persons than was the case a generation or so ago. Lessened needs for high concentrations of hemoglobin may have brought about a physiologic response of lessened production of hemoglobin. The normal adult may find that the simplest means of calling forth a physiologic response to increased production of blood hemoglobin is to engage in active and regular exercise, in other words, to create a need for higher concentrations of blood hemoglobin.

During growth, there is a need for liberal intake of iron to supply the requirements for hemoglobin formation in an expanding blood volume, a condition accelerated during puberty when growth is normally very rapid. Women, because of periodic blood losses, and children because of expansion of blood volume, require larger intakes of iron than men.

The availability of iron salts for nutritional purposes in large measure depends upon their solubilities. The absorption of iron occurs primarily in the uppermost part of the intestinal tract adjacent to the pylorus. With neutralization of the acidity of the gastric juice in this region, the facilities for absorption of iron are diminished. The availability of elemental iron (ferrum reductum) would seem to depend upon the amount that goes into solution as a result of action of the hydrochloric acid of the gastric juice. It is generally assumed that any ferric ions are reduced to the ferrous state prior to absorption. Large amounts of phosphate in the gastrointestinal tract are considered to be unfavorable for the absorption of iron by reason of the formation of insoluble iron phosphate. The iron in ordinary foods varies in degree of availability, and for this reason a good margin of safety is advisable in recommendations of dietary supplies. Egg yolk, meats, whole grain and enriched cereal products, and green leafy vegetables are the most important sources of iron in the average diet. Milk is an outstandingly poor source of iron. For further discussion of the subject of iron in nutrition, readers are referred to a recent article by Heath.²⁴ In conclusion, it is well to mention that anemia results from a variety of causes other than a dietary deficiency of iron, and discussions of these, therefore, do not properly belong in this brief summary of iron in relation to applied nutrition.

Other Minerals. Although iodine occurs in minute traces elsewhere in the body, particular significance attaches to the fact that a large proportion of the body iodine is found in the thyroid gland. Iodine is a constituent of thyroxin, a component of the secretion of the thyroid gland, which in large measure and in conjunction with other internal secretions of the body, controls the rate of energy metabolism of the body. Thyroxin was first isolated from thyroid tissues by Kendall²⁵ in 1914, and has since been synthesized.²⁶ Kolnitz and Remington²⁷ have reported as a result of analyses of the thyroid glands of 150 persons that the average iodine content of the thyroid gland is 8.8 mg.

When the amounts of iodine supplied by food and drinking water are insufficient, the thyroid gland becomes enlarged, resulting in what is called simple goiter. In regions where the soil and water are iodine-deficient, simple goiter has been found to be endemic unless preventive measures are instituted. Iodine of the soil may be derived either from geologic deposition of iodides or from sea-salt, which is relatively rich in iodide. Sea-spray is blown variable distances inland by the wind and may eventually be deposited on the soil as residue from evaporation of the spray, or carried down by rain to the soil and soil water. Regions where geologic deposits of iodine are scant and which are too remote from the seashore to gain iodine from sea-spray have iodine-poor soils and water. In this country, the soil and water in the region of the Great Lakes and large areas in the northwest are distinctly iodine-poor.

Sea foods, including lobsters, oysters, crabs, shrimp, and marine fish are com-

paratively rich in iodine. Garden vegetables grown on iodine-rich soils rank next as natural sources of iodine. The use of iodized salt commonly containing one part of sodium (or potassium) iodide to 5000 parts of sodium chloride is now quite widely and successfully used as a preventive against iodine deficiency. Although wide acceptance of iodized salt has not led to any adverse effects, the Council on Foods of the American Medical Association has recommended²⁸ that individuals over 30 years of age, who have a swelling at the base of the neck, consult a competent physician before using iodized salt. This advice is issued as a caution to those who may have an adenomatous type of goiter which might develop into toxic goiter following ingestion of iodides.

Sulfur is a nutritionally essential element and is a constituent of every living cell. The body tissues contain small amounts of inorganic sulfates. In addition, sulfur is found to occur in body tissues in combination with carbohydrate, with lipids (sulfatides of brain and nerve tissues), and as an integral part of the sulfur-containing amino acids, methionine and cystine, of thiamine (vitamin B₁), of the melanin pigments of the hair and skin, of glutathione (a coenzyme in cellular oxidation-reduction systems) and of the protein insulin, contained in the internal secretion of the pancreas and concerned with the metabolism of glucose.

Although small percentages of inorganic sulfate are contained in foods and frequently in drinking water, by far the greater intake of sulfur is provided in the form of sulfur-containing proteins. By utilizing inorganic sulfates in the soil, plants are able to synthesize the sulfur-containing amino-acids required by man. Rose and his co-workers²⁹ have shown that methionine is an essential amino acid, whereas cystine is not. Apparently methionine alone can supply all the nutritional needs for sulfur-containing amino acids; nevertheless, cystine added to a diet containing a low level of methionine will supplement the growth-promoting properties of methionine. It would seem that cystine could take the place of methionine for some but not all of the functions for which sulfur-containing amino acids are essential.

In applied nutrition, the sulfur requirements are not a problem at all, provided the protein intake is adequate in supplying the kinds and quantities of amino acids that are essential. The sulfur requirements of the body are satisfied when the requirements for sulfur-containing amino acids are satisfied.

Traces of many other inorganic elements have been found in human tissues than those just discussed, some of them would seem to be essential for nutrition and others perhaps present only as casual contaminants. However, it does not *now* appear that many of the trace elements present problems in applied nutrition. This is not a certainty in view of the meager amount of information available on their functional properties, distribution in foods, and quantities that may be required for normal human nutrition. For further information with regard to the trace elements in nutrition, together with a comprehensive list of references, the reader is referred to a recent summary by Shils and McCollum.³⁰

Maintenance of Physiologic Electroneutrality

Obviously all of the ionic constituents in the body contribute to the maintenance of its electroneutrality. The most prominent ionic constituents of the body include sodium, potassium, chloride, phosphatic ions, bicarbonate ions, magnesium, calcium, hydrogen, and sulfate. In addition to these, the small percentages of the so-called trace elements contribute in small degree and in proportion as they occur in ionic form. In view of the uneven distribution of the various ions in the body organs and fluids, it is apparent that electroneutrality of the different parts of the body is maintained by different mechanisms or combinations of electropositive and electronegative ions.

Acid- and Base-forming Foods. The normal acidity of the blood plasma, which serves as an indicator of the acid-base status of the body tissues, is about pH 7.40

(range about pH 7.35 to 7.43). This slight alkalinity is maintained by an intricate system of buffers and through appropriate exercise of excretory functions. Except perhaps in certain diseased states of the body, the acid-base relationships of ordinary dietaries do not affect the acid-base relationships of the body tissues. The pH of the body fluids is maintained with great tenacity, largely through the medium of the lungs which give off CO_2 (the anhydride of H_2CO_3), through excretions from the intestines, and through the medium of urinary excretions, which may be acid, neutral, or alkaline in reaction. The inorganic composition of the food is the principal determinant of the kinds and amounts of inorganic material excreted and of the paths by which elimination from the body is accomplished. In general, the less soluble forms of inorganic matter are the ones most prominent in excretions from the intestines, which, in contrast to the kidney, can excrete inorganic matter in the solid phase. The kidney has the capacity to form NH_4^+ at the expense of urea, thus making it possible to neutralize large excesses of acidogenic ions for excretion without the necessity of sacrificing mineral cations. The ammonia formation is thus relatively large following ingestion of acid or acid-producing foods, and may be small or negligible in alkaline urines.

As eaten, many fruits have an acid reaction due in most cases to potassium acid salts and free organic acids. Whether such foods are potentially acidic or potentially basic in metabolism depends upon whether or not the organic acid radicals are oxidized by the body. A rough estimate of the acid-forming or base-forming values of various foods involves the amounts and proportions of inorganic elements contained in them. Such estimates have been made by Sherman and Gettler³¹ for a considerable number of ordinary food items. In their calculations, the amounts of chlorine, phosphorus, and sulfur were expressed as the equivalent volume of normal acids; the amounts of calcium, magnesium, potassium, and sodium were expressed as the equivalent volume of normal alkali; and the excess of acid or base was obtained by difference. These calculations were based upon the assumption that the sulfur in the foods was completely oxidized; the phosphorus was calculated as the equivalent of a dibasic acid; and no account was taken of such organic acids as might not be oxidized in the body. Nevertheless, for most foods the values obtained do furnish a rough approximation of the acid or alkali values and have shown a fairly good relationship to the effects of the foods on urinary acidity and ammonia excretion. On the basis of such analyses and calculations, meat, eggs, and cereals are shown to be predominately acid-forming foods, while fruits, vegetables, and milk are alkaline-forming in metabolism.

Some years ago, enthusiasm ran high in favor of consumption of foods which would yield an alkaline ash. It was argued that since milk was the natural food for the young of all higher animals and yielded an alkaline ash, a predominately alkaline-forming diet must be desirable, especially for infants and children. Added to that was the argument that the kidneys already were required to excrete an excess of inorganic anions, and acid-ash food put a further strain upon the mechanisms of excretion. However, it has never been possible to demonstrate experimentally or to observe clinically that the acid- or alkaline-ash value of diets composed of ordinary foods is either beneficial or harmful. The question of acid-base relations in the freely-chosen diets of normal individuals no longer commands interest. This summary of the present attitude on the acid-base relation in food is not, of course, to be extended indiscriminately to all individuals, for it is recognized that in certain types of illness, special and individual consideration of this question may be of considerable importance.

VITAMINS IN APPLIED NUTRITION

Vitamins are essential food nutrients. In general, they are regulators for biochemical changes that underlie vital cellular physiology and/or specific tissue mor-

phology. As parts of biologic catalytic systems, they are concerned with energy transformations in the tissues and/or with the orderly building, maintenance and normal functioning of specific tissue structures. The widespread syntheses of the organic compounds, collectively called vitamins, in the plant kingdom have enabled man to be steadily nurtured in part by them and to evolve with a singular dependence upon them.

The B Vitamins. In Fig. 1 (p. 723) are depicted the chemical relationships of thiamine, riboflavin, and nicotinamide in the roles of reversible hydrogen carriers in catalytic dehydrogenating systems. In the chemical combinations indicated, these vitamins take part in many substrate-enzyme-coenzyme systems of fundamental importance in energy transformations in living tissue.

The yeast enzyme, carboxylase, which catalyzes the decarboxylation of pyruvic acid, was found³² to require activation by a thiamine-containing coenzyme (cocarboxylase), which is separable from yeast by washing with alkaline phosphate. By combining the washed yeast and the washing fluid, the capacity to decarboxylate pyruvic acid was restored. It was furthermore noted that the activity of the enzyme-coenzyme system was increased by addition of magnesium salts ($MgCl_2$). Lohmann and Schuster³³ isolated the coenzyme and found it to be a pyrophosphoric ester of thiamine (thiamine pyrophosphate or diphospho-thiamine). As a result of acid hydrolysis or on subjection to the action of kidney phosphatase (alkaline phosphatase), one molecule of phosphoric acid is readily split off, the resulting thiamine monophosphate being without cocarboxylase activity. The second molecule of phosphoric acid is removed by prolonged incubation with kidney phosphatase, the resulting thiamine being without cocarboxylase activity. Alkaline hydrolysis of the thiamine pyrophosphate results in splitting off both molecules of phosphoric acid as inorganic pyrophosphate. The synthesis of thiamine pyrophosphate has been achieved both by enzymatic^{34, 35} and by chemical means.^{36, 37}

It was earlier considered that thiamine pyrophosphate might act as a hydrogen carrier by virtue of alternate oxidation and reduction of the quaternary thiazole nitrogen atom. However, reduction of thiamine or of thiamine pyrophosphate with hydrogen activated with platinum or palladium has yielded biologically inactive products.³⁸ It now appears more likely that the compound oscillates between its reduced state, represented by the usual structure for the vitamin itself and an oxidized state, a disulfide combination, involving two molecules of the vitamin.³⁹ Its reduced and oxidized states, therefore, are analogous to reduced and oxidized glutathione. Thiamine-disulfide is biologically active.

Kubowitz and Lüttgens⁴⁰ have shown that carboxylase consists of three components; protein (one gram molecular weight), thiamine pyrophosphate (one gram molecular weight), and magnesium (one gram atomic weight). In weak acid solution, pH 5 to 6, the three components are very firmly united. At pH 8.1, the enzyme is dissociated, but under suitable conditions, can be reunited with restoration of 85 per cent of its original carboxylase activity.

All the animal tissues examined (brain, skeletal muscle, heart, and liver), contain thiamine, very largely in the form of thiamine pyrophosphate.⁴¹ In thiamine-deficient animals, the concentration of thiamine pyrophosphate in the tissues is markedly diminished; this is accompanied by an accumulation of pyruvate in the tissues, as first noted by Peters.⁴² The administration of thiamine to thiamine-deficient animals brings about a prompt increase in the concentration of thiamine pyrophosphate in the tissues.

There are indications that thiamine pyrophosphate will not readily cross the cell boundaries of body tissues.⁴³ Thiamine absorbed into the blood stream is largely taken up by the liver and kidney, converted into, and stored as thiamine pyrophosphate.⁴⁴ These same tissues can also dephosphorylate the coenzyme^{45, 46} and thus supply free thiamine to the blood stream, whence it can be carried to other body

tissues or be excreted in the urine as circumstances dictate. By such a mechanism, free thiamine can penetrate the cell boundaries and be slowly rephosphorylated within the cells.⁴¹

In animal tissues, thiamine pyrophosphate is primarily concerned with decarboxylation of α -keto acids. In contrast to yeast, which decarboxylates pyruvic acid to yield acetaldehyde and carbon dioxide, in animal tissues the decarboxylation is usually accompanied by dehydrogenation. Whether both the decarboxylation and the dehydrogenation of pyruvic acid in animal tissues are to be ascribed to thiamine pyrophosphate, or whether dehydrogenation is carried out through the medium of a second vitamin-containing coenzyme (diphosphopyridine nucleotide) has not been settled, but it would appear that the second mechanism is the more probable, so far as can be judged at present.

Riboflavin in the role of coenzyme acts by reversibly accepting or releasing two atoms of hydrogen, a property also shown by the free flavin and observable in the reversible shift between the yellow color of the oxidized form and the colorless product representing the dihydro form of the vitamin.^{47, 48, 49} The redox potential of an equimolar mixture of riboflavin and dihydro-riboflavin is -0.21 volt (pH 7.0, and referred to a normal hydrogen electrode). In the role of coenzyme, riboflavin participates in many oxidation-reduction reactions in animal tissues, its part being played in each case by virtue of its capacity to transport hydrogen. These reactions are catalyzed by specific enzymes. Nicotinic acid amide, another vitamin of the B-group, is also known to act in several enzyme systems concerned in carbohydrate and protein metabolism of animal tissues.^{50, 51} And again the function of the vitamin is that of a hydrogen carrier, although this may not be the only means by which it acts in biologic processes. The coenzyme combination of this vitamin, diphosphopyridine nucleotide, forms an internal salt, the positive charge on the N of the pyridine structure balancing a negative charge on one of the phosphate residues, as can be seen from the structure of this coenzyme. The isoelectric point of this coenzyme is at pH 3. The hydrogenation sets in at the $N=C$ double bond in the pyridine nucleus, while the nitrogen becomes trivalent; one hydrogen becomes ionized. With reduction of the pyridine nucleotides the ultraviolet absorption band at 260 m μ , referable to the adenine structures, is observed to sink slightly and a strong band appears with a maximum of 340 m μ . Furthermore, the dihydro derivatives of the pyridine nucleotides fluoresce white in ultraviolet light. These characteristics make it possible to measure the course of the reduction in systems comprised of substrate-enzyme-pyridine nucleotide.⁵⁰

In seeking an over-all picture of the role of B-vitamins in chemical reactions of tissues, it should be pointed out that the energy released from oxidations of food-stuffs is not all immediately set free. Energy is made available to the cell for a variety of syntheses for which a source of energy is required. Oxidative energy, for example, is transformed into so-called "phosphate bond energy" in such forms as adenosine triphosphate and creatine phosphate which constitute the immediate source of mechanical energy of muscle, and of course food energy in excess of the body's needs is largely stored as body fat. The Warburg school conceives the chemical entities, sketched in Fig. 1 with B-vitamin nuclei in their structures, as *active groups* of specific proteins in combination with which they comprise distinct enzymes. This conception regards the large array of dehydrogenases as conjugated proteins analogous to phosphoproteins, nucleo-proteins, etc. According to this concept cocarboxylase or thiamine pyrophosphate, for example, would be regarded as the active or prosthetic group of a specific protein which catalyzes the decarboxylation and carboxylation of aliphatic α -keto-acids such as pyruvic acid; the protein, prosthetic group, and magnesium together comprising the complete enzyme. The structure of thiamine pyrophosphate is shown in Fig. 2. However, in the light of recent developments it would seem more appropriate to consider chemical combina-

tions in which the B vitamins act in many cellular catalytic reactions as *distinct parts* of substrate-enzyme-coenzyme systems. The structures of the coenzymes, flavin-adenine-dinucleotide and diphosphopyridine nucleotide are shown in Figs. 3 and 4 respectively. Nicotinamide also constitutes a part of at least one other coenzyme, triphosphopyridine nucleotide, which differs from the structure shown in Fig. 4 by inclusion of a third phosphoric acid residue. In addition to their role as hydrogen

carriers, the pyridine nucleotides are also known to take part in some of the phosphorylation reactions of tissues.⁵¹

Certain dehydrogenations conducted *in vitro* with enzymes and substrates, which in biological environments require the presence of the coenzyme triphosphopyridine nucleotide, can proceed without an intermediary coenzyme to transfer the hydrogen from substrate to acceptor.⁵² So the hydrogen-carrying coenzyme is necessary only when certain acceptors are used. And by the same token it may be concluded that nicotinamide is essential for dehydrogenations in living cells because of the particular hydrogen acceptors available to receive the hydrogen from the oxidized substrate. This may presage an observation that not all living organisms incapable of synthesizing nicotinamide will be found to require nicotinamide as a preformed nutrient. It would also seem that this observation is opposed to the concept that coenzymes, such as the pyridine nucleotides, are actually prosthetic groups of dehydrogenases, since these dehydrogenases have now been observed to catalyze certain dehydrogenations in the absence of coenzyme, which they would be unable to do if the coenzyme structures were essential for the activity of the enzymes. The simplest picture of

the substrate-enzyme-coenzyme relationships of such dehydrogenating systems as involve the B vitamins as essential parts of hydrogen-carrying coenzymes may be visualized as follows: The substrate forms a highly dissociable compound with a very specific group in the enzyme whereby the substrate is "activated," that is, made more tractable to giving up some of its hydrogen. The coenzyme also combines with the enzyme, likewise forming a highly dissociable compound. Two hydrogen atoms then pass from the combined substrate to the combined coenzyme. The dehydrogenated substrate and the hydrogenated coenzyme then leave the enzyme, the former usually to be further dehydrogenated and the latter to be reoxidized by an appropriate redox system. The enzyme meanwhile is free to combine with further molecules of substrate and coenzyme, and the process is repeated. After a one-step oxidation of a given substrate by a hydrogen-carrying coenzyme in the presence of the enzyme specific for the reaction, the resulting oxidation product can act as a substrate in another substrate-enzyme-coenzyme system, and so on in succession to complete oxidation, the energy of food being thus released through a series of catalytic oxidations. Simultaneously the hydrogen taken up by the coenzymes is transported from one cellular redox system to another, until finally it can be transferred to molecular oxygen brought to the tissues by oxygenated blood. This hydrogen transport system is catalyzed by specific enzymes.

Pyruvic acid, which appears early in the oxidative breakdown of carbohydrates in living tissues, is not only an intermediate in the metabolism of carbohydrate, but also of protein and probably of fat as well. The flavin-containing coenzyme, flavin-adenine-dinucleotide, together with a specific enzyme, can catalyze the oxidative deamination of *D*-amino acids, that of *D*-alanine yielding pyruvic acid.⁵³ It is generally assumed that the biologically *L*-amino acids *in vivo* also form pyruvate in the course of their metabolism. Pyridoxine has recently been reported to be associated with the utilization of unsaturated fatty acids,^{54, 55, 56} and to be essential to animals for the production of fat from protein,⁵⁷ the latter involving, it is assumed, preliminary synthesis of carbohydrate or carbohydrate derivatives such as pyruvic acid, which can subsequently be converted into fat. The conversion to fat also requires a supply of thiamine. It would appear, therefore, that pyruvic acid occupies a central field position in most energy transformations involved in living tissues.

In Fig. 5 is shown the so-called "citric acid cycle" of Krebs,⁵⁸ which is quite widely accepted as representing the main path of carbohydrate oxidation in various body tissues.* The cycle, as represented, rests on excellent experimental support and represents a cyclic chain of chemical transformations summarizing the main points of current knowledge concerning pyruvate oxidation in various animal tissues.⁵³ When this scheme first appeared, the product fed into the cycle was termed "triose" or "carbohydrate derivative" and later was replaced by pyruvate, subject to further inquiry. Since pyruvate has been shown to react in preference to other substances, and since such other substances as may react here can be oxidized to pyruvate in muscle tissue, we may visualize the whole process as hinged upon pyruvate oxidation. Pyruvate then feeds into this cycle where, in the presence of oxygen, it condenses with oxalo-acetate to form citrate, or possibly to form *cis*-aconitate, which is broken down by a series of enzymatic reactions to oxaloacetic acid. The complete cycle effects a total oxidation of pyruvic acid to carbon dioxide and water. Considering the chain of reactions as depicted by the succession shown by reading in a clockwise direction, it is clear that the cycle involves the transfer of six pairs of hydrogen atoms; thus the complete cycle effects a total oxidation of pyruvic acid to water and carbon dioxide.

In isolated systems and in work with various tissue preparations it has been found that the coenzymes, flavin-adenine-dinucleotide, diphosphopyridine nucleotide and triphosphopyridine nucleotide (the first containing riboflavin and the latter two nico-

* See Addendum at the end of this paper.

FIGURE 5. Kreb's citric acid cycle.

tinamide structures) participate in reactions shown as parts of the so-called Krebs cycle. And, as mentioned earlier, thiamine participates in controlling the rate of pyruvate utilization by the tissue. Although the chemistry of the B-vitamins as they relate to the intimate energy metabolism taking place in tissue cells is not entirely in the category of a system of successive, well established chemical reactions which will elucidate all of the intricate detail involved, great progress has nevertheless been made in a better understanding of cellular energy transformations.

The specific functions of the more recently discovered members of the B-group of vitamins are only beginning to be investigated. In view of the close interlocking and interdependence of the reactions catalyzed by the enzyme-coenzyme systems of which the B-vitamins are constituent parts, it is easy to comprehend why the signs of respective deficiencies of these in man are *not always* clearly circumscribed. Probably in the ordinary course of events most clinical manifestations ascribed to a deficiency of any one of the group of B-vitamins represent a multiple-deficiency state. In the final analysis, it appears that the deficiency of one B-vitamin may block off some of the chain of successive reactions in which other vitamins of this group act as coenzymes, and that restoration of the specific shortage might operate as both a primary and secondary corrective mechanism. The *terminal* pathology of the various B-vitamin deficiency states seems to be fundamentally the same and dependent upon disturbed oxidation in the tissues. Physical weakness or tiredness, as one would expect with disturbed tissue respiration, is evident in any B-vitamin deficiency state.

The induced B-vitamin deficiency states in man and animals, under controlled conditions, may be more an illusion than a reality when the deficiency of one may

conceivably block the normal functioning of another. Often fatigability and a very red mouth and tongue are the only evidence indicative of some B-vitamin deficiency state, rapidly brought on as a result of disease which interferes with normal assimilation of one or more of these vitamins. In such cases, the very red mouth and tongue return to normal tints fairly promptly when the missing vitamin or vitamins are supplied so that the body can use the oxygen of arterial blood; otherwise the degree of oxygen saturation in venous blood approaches that of arterial blood, a fact which explains the redness of the tissues mentioned.

The frequent occurrence of varying degrees of thiamine and nicotinic acid deficiency states in chronic alcohol addicts has been more or less popularized in the public mind. The explanation most commonly offered is that the food consumed by the chronic alcohol addict is usually inadequate in quantity and decidedly deficient in protective food values, prominently so in the B-vitamins. The metabolism of alcohol is not known in its entirety, but according to recent information,⁵⁹ the first two steps are presumably as follows:

The enzyme, alcohol dehydrogenase, which is concerned with the first step in oxidation of alcohol (to acetaldehyde) is found almost exclusively in the liver. This statement is based on alcohol perfusion experiments and studies on liver poisoning. In this first step, one of the coenzymes containing nicotinamide is believed to act as the hydrogen carrier. The second step, which involves the condensation of acetaldehyde and pyruvic acid, requires thiamine pyrophosphate.⁵⁹ Therefore, the chronic alcohol addict is burning his candle, so to speak, at both ends—his diet is deficient in thiamine and nicotinic acid values; the principal source of his calories (alcoholic beverages) carry little or none of these two vitamins, and yet both of these vitamins are just as essential for alcohol metabolism apparently as for the metabolism of carbohydrates from food. It might be of interest to point out here too that the ingestion of alcohol increases the blood sugar level (mobilized from glycogen in the liver if necessary) as a corollary to the mode of its metabolism; and its oxidation or disappearance, therefore, is delayed if the glycogen stores in the liver are relatively near exhaustion. If the glycogen stores of the liver have been exhausted, a more rapid disappearance of alcohol is favored when it is ingested along with some readily available form of carbohydrate such as sugars.

The respective signs of thiamine, riboflavin, and nicotinic acid deficiencies and the pathology of the body tissues of man and other animals suffering from a deficiency of one or more of these vitamins will not be discussed further here except to mention that they are but the manifestations or terminal results of default in the biochemical reactions catalyzed by the respective coenzymes depicted in Fig. 1.

The B-vitamins seem to be universally important wherever energy transformation in living matter takes place or is provided for by nature. The vitamins in dormant seeds include, in most cases at least, all those mentioned in the previous discussion. As new plants spring from seeds, these vitamins are undoubtedly a prime factor in the energy transformations involved. It is also apparent that plants must synthe-

size these vitamins in parts most intimately concerned in their respiration, namely, the leaves, and from this synthesis presumably the seeds derive their vitamins. In animals those tissues, where oxidative processes are most in evidence, are found to have the highest relative concentrations of B-vitamins, in descending order the liver, heart, kidney, and muscles. The muscle of swine, by comparison with that of other species, is remarkably rich in thiamine. One could easily surmise, and there is some evidence to the point, that this may be associated with the tremendous capacity of swine to transform carbohydrate into fat.

Since thiamine, riboflavin, and nicotinic acid (actually its amide) are concerned with cellular oxidations; are not capable of being stored in the body to any large extent; are known to be destroyed in part in the tissues; are capable of being excreted by the kidney (as vitamins or products derived from vitamins); and are intermeshed with one another in cell respiration, it is obvious that the body's requirements for these vitamins are distinctly related to the sum total of energy metabolism, are required day by day, and probably are required in definite proportion to one another. According to very recent work⁶⁰ 0.45 mg of thiamine per 1000 calories of diet contributed by protein, fat, and carbohydrates in proportions conventional for the majority of American diets, appears to be approximately the level of intake required to prevent all but perhaps very mild degrees of biochemical defects in pyruvic acid metabolism. The Food and Nutrition Board of the National Research Council²¹ has listed tentative daily allowances of thiamine for persons of seventeen age-sex-activity groups. These allowances, weighted on the basis of the 1940 census of composition of our population, reduce to 1.6 mg of thiamine per capita per day. Computations based on governmental surveys of dietary habits and thiamine analyses of the foods as eaten⁶¹ indicate that for the few years prior to 1940 the average American diet provided only about 0.9 mg of thiamine per capita per day (or about 56 per cent of the recommended daily per capita allowance). Although concrete evidence such as that just summarized was lacking until very recently, evidence of various kinds pointed to the fact that enrichment of white flour with thiamine would be in the interest of better nutrition for the American people. This idea has now been extended to include thiamine, nicotinic acid, riboflavin and iron. Without going into the history of progress along the way, it can be said that developments have now reached the stage where it is expected that before the end of the year 1943 all family white flour will be enriched to carry 2.0 mg of thiamine per pound and all commercial white bread will be made from enriched flour or will carry the equivalent enrichment from other sources. When this program becomes effective, the average peace-time American diet will provide about 1.46 mg (or 91% of the per capita daily allowance) of thiamine which is contributed by various food classes as follows: meat, fish and poultry 16 per cent, dairy products 13 per cent, flour and cereals 53 per cent, vegetables 12 per cent, and fruits 6 per cent. No precise statement can be offered with regard to the magnitude to which unequal distribution may effect individuals. However, since flour and cereals, which contribute in largest measure to the thiamine value of the diet are among the least expensive types of foods, any shortages due to unequal distribution of foods should not particularly affect persons of relatively limited income.

In view of the relation of riboflavin to tissue oxidation, it would seem that, as in the case of thiamine, the daily requirement for riboflavin must be proportionate to energy metabolism. Earlier reports,^{62, 63, 64} upon which the tentatively recommended daily allowances for riboflavin were largely based, indicated that the riboflavin requirement of man might be a little less than 0.06 mg per kilogram of body weight. More recent and more thoroughgoing work however has provided good evidence that 0.5 mg of riboflavin per 1000 calories contributed by an ordinary mixed diet provides for satisfactory tissue stores of this vitamin.⁶⁵ The average daily per capita allowance of calories for our present population amounts to 2800, and

on this basis the riboflavin allowance would be 1.4 mg per capita per day. This figure represents the best estimate available at present. For the few years prior to 1940 the average American diet, corrected for riboflavin losses in food preparation,⁶⁶ provided about 1.4 mg (or 100 per cent of the estimated allowance) of riboflavin per capita per day. With enrichment of family white flour to the proposed level of 1.2 mg per pound of flour and of commercial white bread, either through the use of enriched flour or by equivalent enrichment from other sources, the average peace-time American diet will provide about 1.9 mg (or 34 per cent excess over the estimated per capita need) of riboflavin. The riboflavin contributions of various food groups will then be as follows: dairy products 42 per cent, flour and cereals 30 per cent, meat, fish and poultry 16 per cent, vegetables 9 per cent and fruits 3 per cent. The extra allotment of riboflavin can probably be justified in times of certain food shortages, but it is not an adequate substitute for application of the newer knowledge of nutrition, for a progressive agricultural program which will insure adequate amounts of the basic foods in American dietaries, nor for solution of the economic ills of the country.

The human requirements for nicotinic acid are not well established. The tentative daily allowances recommended by the Food and Nutrition Board,²¹ when computed for the seventeen age-sex-activity groups specified and weighted by the number of persons in each group on the basis of the 1940 census of population amounts to 16 mg per capita. The average per capita intake of nicotinic acid was until recently estimated⁶⁶ at approximately 77 per cent of the recommended allowance. With enrichment of all commercial bread and family white flour at the levels now in process of adoption, the full per capita quota will be met with a reasonable margin of excess. The proposed standard for nicotinic acid-enrichment of white flour is 16 mg per pound of flour. The common foods which contribute most significantly to the nicotinic acid intake of the American people include lean meats, and enriched white flour and bread. Normally these two classes of foods will provide about 94 per cent of the per capita daily allowance of nicotinic acid. Milk, fatty meats, cornmeal, fruits, and vegetables contain small amounts. In view of the endemic occurrence of pellagra in certain sections of this country, it is apparent that there has been and still is, in lesser degree, an uneven distribution of nicotinic acid-containing foods. Solution of this problem of applied nutrition calls for expansion of nutrition education and probably some economic readjustments.

Many other more recently discovered members of the B-vitamin group will undoubtedly prove to be of significance in human nutrition. Some of them, for example, pantothenic acid and biotin, are apparently concerned with tissue respiration. Pantothenic acid, (α , γ -dihydroxy- β , β -dimethylbutyryl- β -alanide) has been isolated⁶⁷ and synthesized.⁶⁸ It is apparently a constituent of all living tissues, and in consequence may be expected to have broad physiologic importance. By the same token, the chances of pantothenic acid deficiency states in man are reduced. Although a dietary deficiency of this vitamin has been observed by numerous investigators to be associated with symmetrical depigmentation of the hair or fur of animals, from which it may be inferred that it has some effect on the metabolism of melanin pigments, the mechanism of its action related to this property is not clear. Before applying this knowledge, it is well to note that pyridoxine, another vitamin of the B-group already mentioned, and with which pantothenic acid is often associated in nature is reported to promote or accelerate the graying of hair.⁶⁹

Biotin was isolated^{70, 71} and synthesized⁷² in 1943. The structural formula for this vitamin is shown in Fig. 6. Three independent lines of research involving a nutrient essential for yeast growth, a nutrient essential for the growth of *Rhizobium*, a nitrogen-fixing bacterium,⁷³ and a substance capable of inhibiting in animals the deleterious effects of feeding raw egg white,⁷⁴ finally culminated in the knowledge that the three biologic effects were attributable to the same chemical entity, currently

referred to as biotin. The story of the convergence of these three parallel lines of investigation, which finally merged into the discovery that one substance accounted for all three biologic phenomena, is already familiar to students of nutrition and has been adequately presented⁷⁵ elsewhere. Biotin is widely distributed in the plant kingdom and also in animal tissues. Its significance in human nutrition is not known, but, from preliminary indications, it may play an important role as a catalyst in cellular respiration.

FIGURE 6. Biotin.

Inositol, para-aminobenzoic and folic acid (a vitamin-like substance found in green leaves), may also be considered members of the expanding family of B-vitamins. All are widely distributed in nature but their fundamental significance in human nutrition is only beginning to be investigated. Several of the more recently discovered members of B-vitamin group are synthesized by the bacterial flora in the gastro-intestinal tracts of animals. This phenomenon is very prominently featured in animals with spacious rumen.

Many of the B-vitamins stimulate the growth of microorganisms, which in turn, and as a result of growth, produce further quantities of B-vitamins. Ruminants probably are provided with a considerable proportion of their requirements for certain B-vitamins as a result of vitamin syntheses in their gastro-intestinal tracts. Under ordinary circumstances, other animals probably derive a part of their requirements for B-vitamins as a result of bacterial syntheses followed by subsequent absorption of these vitamins from the gastro-intestinal tract and in part from plant and animal tissues used as food and in which certain members of the group of B-vitamins appear to be almost universally present. This may be the case with man also but the question of which B-vitamins and to what extent man obtains them by reason of the growth of intestinal flora is a problem for the future. Those B-vitamins for which fairly well-established human requirements or tentative estimates of requirements have been mentioned in this chapter, however, must be given practical considerations in food selection, since otherwise specific vitamin-deficiency diseases will develop.

Ascorbic Acid. All intercellular substances of bone, cartilage, dentine and fibrous connective tissues have a common type of protein-substructure known as collagen, for the setting, fibrillation, or jelling of which ascorbic acid is a necessary agent.⁷⁶ The fundamental function of ascorbic acid is therefore concerned with the formation and maintenance of intercellular materials.

Ascorbic acid is not a dietary requirement of all species of animals nor even of all mammals, some of which can synthesize this vitamin. It is a dietary requirement of primates, including man and monkeys, and of guinea-pigs.

In ascorbic acid deficiency states in the young, there develops retarded or defective production of intercellular matrices in bone, dentine, and connective tissues; with prolongation of the deficiency, all deposition of intercellular substances ceases and there sets in a slow resorption of matrices previously laid down. In scorbutic states, generally, the organic matrices of the supporting tissue structures become dis-

organized and are slowly resorbed, in consequence of which the minerals previously deposited in the teeth and bones are also resorbed.⁷⁶ This explains in brief the marked osteoporosis associated with severe scurvy.

The normal and complete repair of wounds is dependent upon the action of ascorbic acid by virtue of the latter's essential function in the formation of normal intercellular materials.

The mechanism by which ascorbic acid promotes the formation and maintenance of normal intercellular material is unknown.

The most obvious chemical property of ascorbic acid is its capacity for reversible oxidation and reduction, which can be depicted as follows:

Glutathione, a substance already mentioned as being concerned in tissue respiration, possesses the capacity of reducing the oxidized form of ascorbic acid. It is more than likely that the reversibility of the oxidized and reduced forms of ascorbic acid which impart the property of a hydrogen transporter to this vitamin is of major importance in the physiology of the body tissues.

The principal sources of ascorbic acid in human dietaries include the citrus fruits, tomatoes, and green leafy vegetables. In quantities commonly consumed, potatoes can, if properly prepared, provide a large share of the dietary requirements for ascorbic acid.

There is some question as to whether or not the body derives any special benefit from saturation of the tissues with this vitamin over and above maintenance of some lesser concentration. Tissue saturation with ascorbic acid is demonstrated by a prompt and precipitous rise in the ascorbic acid level in the blood plasma following the administration of large doses (on the order of 8 mg or more per kg of body weight) of ascorbic acid, the rise in ascorbic acid level in the plasma being accompanied by urinary excretion of a large part of the ingested vitamin. For the maintenance of tissue saturation with ascorbic acid, infants under six months old require daily on the order of 2.0 mg of ascorbic acid per kg of body weight,⁷⁷ while older children⁷⁷ and adults²¹ require about 1.0 mg per kg of body weight. It should be noted here that the normal requirements for this vitamin are proportional to body weight, an observation which is in accord with the function of this vitamin in maintenance of normal tissue structures.

The Fat-soluble Vitamins. Vitamin A or some carotenoid precursor which has the β -ionone ring and conjugated side chain structure characteristic of Vitamin A is essential for normal action of the retina in dim light and probably in other aspects of visual processes. It has been known at least since 1500 B.C. that eating the livers of animals which are now known generally to be rich sources of vitamin A was an effective means of restoring certain types of impaired dark adaptation. The recent work of Wald and his associates⁷⁸ has offered considerable new advance in understanding the chemical basis of dark adaptation. The visual cycle as it relates to the role of vitamin A in dark adaptation and as depicted by Wald is shown in Fig. 7.*

* See paper by George Wald in this volume. J. A.

FIGURE 7. Rhodopsin cycle in visual adaptation.

The sensations of light are due to nerve impulses initiated by changes in light sensitive-materials in the retina. When light reaches the visual purple pigment or, more strictly speaking, the rhodopsin in retinal structures, of the mammalian species, some of the rhodopsin is broken down in the first stage to another pigment known as retinene and a protein and in a second stage to vitamin A and protein. The protein constituent of visual purple appears to be a globulin and to be joined to phospholipid to form a phospho-protein.⁷⁹ For a given intensity of light a corresponding equilibrium in the concentrations of materials shown as parts of this cycle becomes established. If then the light is extinguished, a new equilibrium gradually establishes itself with a greater proportion of rhodopsin being regenerated. In vitamin A deficiency attended with nutritional night-blindness, the equilibrium established for the dark-adapted eye is such that vision in dim light is impaired, and the light threshold is raised. Some years ago Fridericia and Holm⁸⁰ observed that, whereas the retinas of light-adapted eyes could be readily detached from the choroid layer underneath, in dark-adapting eyes the retina adhered closely to the choroid layer which is known to contain numerous blood capillaries. It would appear that the level of vitamin A in blood plasma was the determining factor in the presence or absence of nutritional night-blindness. Under ordinary circumstances the level of vitamin A in blood plasma appears to remain fairly constant so long as the vitamin A supply in the food is adequate, or so long as substantial vitamin A reserves are present in the liver. Lacking an adequate supply in the food or appreciable reserves in the liver, nutritional night-blindness results and progresses as the state of vitamin A deficiency is prolonged.

Vitamin A is also essential for the normal development and maintenance of epithelial structures which cover the free surfaces of the body (cutaneous, mucous, serous, and including the glands) and for promotion of the normal functioning of these structures. The so-called enamel organ, an epithelial organ which plays a leading role in the formation of organized tooth structure, atrophies and undergoes morphologic changes as a result of vitamin A-deficiency. A characteristic paralysis has been noted for many years to be an accompaniment of a dietary deficiency of vitamin A in young experimental animals. This has recently been shown to result from the fact that following deprivation of Vitamin A, the central nervous system and other soft tissues continue to grow at approximately normal rates after the growth of bone has been greatly slowed up. With complete cessation of growth, this disproportion of body parts remains. The brain and spinal cord and nerve roots suffer mechanical damage as a result of being overcrowded in the cranial cavity, the tract of the spinal cord, and intervetebral foramina respectively. The nervous lesions in vitamin A-deficiency are thus explained as being wholly mechanical in origin. All the functions of vitamin A, and the pathologic lesions attendant upon a deficiency of vitamin A mentioned in this paragraph, have been systematically reviewed and discussed recently by Wolbach and Bessey,⁷⁶ who have also contributed in very large measure to present knowledge of this subject.

Vitamin A is abundant in common foods. All dark green leaves, all deep yellow-

colored vegetables (carrots, sweet potato, pumpkin) and fruits (apricots, persimmons, muskmelons and peaches), fish-liver oils and livers of all well-fed animals are rich sources of Vitamin A by virtue of containing either Vitamin A or its esters or by being rich in vitamin A-active carotenoids (alpha, beta and gamma carotene and cryptoxanthin). Milk and eggs are good sources of Vitamin A and many other foods contain small amounts of this vitamin. Probably it could be stated with more than a modicum of truth that a dietary insufficiency of this vitamin can result, under ordinary conditions which prevail in this country, only through ignorance of the simplest facts about food values.

During World War I, evidence of rather widespread vitamin A-deficiency leading to blindness among Danish children was reported,⁸¹ and was attributed to the fact that butter and whole milk were so scarce and expensive as to make it impossible for those with low or moderate incomes to provide their children with these foods. The incidence of the disease (xerophthalmia) was checked by the German blockade, which prevented export of butter and by the fact that the butter thus made available was rationed.

Booher *et al.*⁸² have reported that from 8 to 17 micrograms of vitamin A per kilogram of body weight per day are required to prevent impaired dark adaptation in adults, which finding has been confirmed by Wagner⁸³ and others. Lewis and Haig⁸⁴ have reported essentially similar daily vitamin A requirements (per kilogram of body weight) for the prevention of impaired dark adaptation in infants 1½ to 10½ months old. The minimum daily intake of carotene required for the prevention of impaired dark adaptation in adults, when supplied in the form of commercial carotene (85 per cent beta- and 15 per cent alpha-carotene) dissolved in cottonseed oil varied between the limits of about 26 and 62 micrograms per kilogram of body weight.⁸² At least part of the relatively large differences between minimum vitamin A requirements in terms of vitamin A from cod-liver oil and those in terms of carotene (one microgram of vitamin A is the biologic equivalent of about two micrograms of β -carotene) are probably due to the relatively poorer absorption of the carotene.⁸⁵ In terms of biologic equivalents, β -carotene was only about 50 to 60 per cent as effective as the vitamin A in cod-liver oil in the maintenance of normal dark adaptation. The carotene in spinach or in green peas was somewhat better utilized than carotene itself.⁸⁶ From observations of Guilbert *et al.*⁸⁷ on cattle, sheep, and swine, in conjunction with those on man, it would appear that the daily vitamin A (and/or carotene) requirements on a body-weight basis were possibly of the same order for all mammals.

Vitamin E is reported^{88, 89, 90} to exert a sparing effect upon vitamin A, and more so on carotene, resulting in improved utilization of vitamin A or carotene for growth and vitamin A storage. The antioxidant property of vitamin E has been known for some time, and it is assumed that this property manifests itself in the gastro-intestinal tract to check the destruction of vitamin A and carotene, thus exerting indirectly a sparing effect on these. It has also been found⁹¹ that previously accumulated stores of vitamin A in the livers of animals are more slowly depleted when the animals are transferred to a vitamin A-deficient diet if vitamin E is provided than if the animals are deprived of vitamin E. Whether or not this sparing effect of vitamin E on the utilization of accumulated body-stores of vitamin A is the result of the antioxidant properties of vitamin E has not been determined.

The vitamins E (alpha, beta, and gamma tocopherol) occur chiefly in vegetable oils (wheat-germ oil, cottonseed oil, and other seed oils), in olive oil and in green leaves. A deficiency of vitamin E in the diets of animals has been shown to result in reproductive failure and in severe and generalized degeneration of the skeletal muscles (so-called nutritional muscular dystrophy), which phenomena has been the subject of intensive studies in recent years. The pathology of the vitamin E-deficiency state has been summarized in the article of Wolbach and Bessey,⁷⁶ who have

included in their review a comprehensive list of references to original published reports on this subject.

The necessity for vitamin E in the human dietary has not been established. If it is an essential nutrient for man, the needs are not likely to present any major problem in the practical applications of nutrition, since this vitamin is very widely distributed in common foods.

Vitamin K, sometimes referred to as the anti-hemorrhagic vitamin, occurs in nature in at least two forms, designated as K_1 (in green leafy vegetables) and K_2 (produced by bacteria). The first evidence pointing to the existence of vitamin K was reported by Dam,⁹² who observed the development of extensive subcutaneous intramuscular hemorrhages and a delay in blood-clotting time in young chicks as a result of feeding them a special fat-free diet.

Vitamin K is essential for maintaining a normal prothrombin level in blood.⁹³ Marked lowering of the prothrombin level of the blood (to about 20 per cent of its normal value) is attended with delayed blood-clotting time. The mechanism by which vitamin K functions to maintain normal prothrombin levels in the blood is not known. The so-called hemorrhagic disease occasionally observed in new-born infants is tractable to vitamin K therapy. Some clinicians have recommended administration or injection of vitamin K for the new-born infant or for the mothers shortly prior to the birth of the infant as a precautionary measure. After the first few days of infant life, vitamin K is normally produced by bacterial action in the intestinal tract, from which in the presence of bile, it can be absorbed and utilized for the maintenance of normal prothrombin levels in the blood.

The naturally occurring vitamins K are fat-soluble and require the presence of bile salts for their absorption from the intestinal tract. Individuals with biliary obstructions may develop K-avitaminosis, notwithstanding the fact that their food may have contained adequate amounts of Vitamin K.⁹⁴ As indicated in this discussion, there is little need for concern about adequate provision for vitamin K for the normal individual. K-avitaminosis is largely a problem of the clinician who has had made available to him the necessary materia medica with which to combat it.

Several synthetic products, possessing vitamin K-activity, have been developed, and some are being used for medicinal purposes. The most biologically active synthetic compound is 2-methyl-1, 4-naphthoquinone,⁹⁵ which possesses about three times the potency of natural vitamin K, (2-methyl-3phytyl-1, 4-naphthoquinone).⁹⁶

The term "vitamin D" is applied to substances of a sterol nature, which possess antirachitic activity. Vitamin D, as such, occurs in significant amounts in very few foods other than fish-liver and body oils. At least ten different sterols, known as provitamins D, can be activated to vitamins D by irradiation with ultraviolet light or by bombardment with cathode rays.⁹⁷ The conversion of provitamin D to vitamin D is not a simple process, since many intermediate compounds are formed and the resulting Vitamin D is also capable of transformation into other products. Thus, from a mixture of substances, there is just one that possesses vitamin D activity and the others are closely related contaminants, some of them highly undesirable or toxic. Slight alterations in the conditions of activation will cause changes in the relative proportions of the products formed.

The provitamin D most prominent in plants or more specifically in molds and yeast is ergosterol. The provitamin D most prominent in man and domestic animals, where it exists largely in the skin, is 7-dehydro-cholesterol. Activated ergosterol is also known as Vitamin D₂, calciferol, or viosterol. The most prominent D-vitamin in fish-liver oils is Vitamin D₃, which is identical with activated 7-dehydro-cholesterol and is, therefore, the Vitamin D formed in the skin as a result of its exposure to ultraviolet rays from the sun and sky.

Vitamin D is essential for normal growth sequences in bone and for normal mineralization of bone. The deleterious effects of a deficiency of vitamin D on

teeth (defective calcification of the enamel and dentine and atrophy of the developmental organs of these structures) are most marked during the period of tooth formation.⁷⁶

Lack of vitamin D alone will produce rickets in infants. Satisfactory mineralization of the skeleton of infants, however, requires adequate supplies of calcium, phosphorus and vitamin D. Osteoporosis, the adult counterpart of rickets, probably results from a deficiency of vitamin D together with a relative deficiency of calcium or phosphorus in the diet, or a decidedly low intake of one or the other or both of these inorganic nutrients.⁷⁶

There is no evidence which indicates a local effect of vitamin D at the zone of deposition of calcium and phosphorus in the bone matrix. Vitamin D functions chiefly, it is believed, by increasing the efficiency of absorption of calcium and phosphorus from the digestive tract. By so doing, it promotes the maintenance of normal concentrations of calcium and phosphate ions in the blood plasma so that calcification of the skeleton can take place. There is some evidence which indicates that the means by which vitamin D increases the efficiency of absorption of calcium and phosphorus is through lowering of the pH of the gastro-intestinal contents.

Vitamin D values of foods and medicinal preparations are usually expressed in terms of units. One International Unit or one U. S. Pharmacopeia Unit is equivalent to about 0.025 microgram of vitamin D₂. The primary vitamin D reference standard is a solution of irradiated ergosterol (made under specified conditions) in olive oil. The solution contains one milligram of the activated ergosterol in 10 ml of olive oil. A unit of vitamin D is one milligram of this solution. Secondary standards are prepared on the basis of biologic assays wherein the criteria of equivalence of primary to secondary standard is estimated by the quantities of the two required to promote a definite degree of healing in rachitic animals.

Infants receiving adequate quantities of milk require about 135 units of vitamin D daily in order to be fully protected from rickets, but they require from 350 to 400 units of vitamin D to support a satisfactory rate of growth and good mineralization of the skeleton.⁹⁸ Daily intakes of the same general order of magnitude are required throughout childhood, and similar quantities are advocated for women during periods of pregnancy and lactation.²¹

The administration of excessive amounts of vitamin D (of the order of 1600-1800 units per day) to infants, causes a retardation of growth,⁹⁸ an observation which has substantiation in the histologic changes observed to develop as an accompaniment of excessive intakes of vitamin D in animals.⁷⁶

There would appear to be no important difference in effectiveness for the human species between Vitamin D₂ and Vitamin D₃.⁹⁸ The vitamin D requirement of average adults has not been established. A part of the adult's requirement is provided as a consequence of exposure to sunshine and sky shine, but it is probably to the best interests of the average adult to take vitamin D in some form, up to quantities of 350 or 400 units daily if their lives are largely spent indoors.

Except for appreciable quantities of vitamin D in herring, salmon, tuna, and sardines, all of which are classed as fatty fish, foods are unimportant sources of vitamin D. The quantities of vitamin D in butter, milk, cream, cheese, and egg yolks produced under ordinary conditions, are small and variable. They depend upon the degree to which the animal or fowl producing the food has been effectively exposed to ultraviolet light or fed foods rich in Vitamin D. Animals and fowls are not efficient in their transference of Vitamin D from their bodies to such products as milk and eggs. The practical alternative for enhancing the vitamin D values of foods is to activate the foods themselves by irradiation with ultraviolet light or to add concentrates of vitamin D to them. Both of these means have been applied to preparation of Vitamin D milk. In the judgment of many nutritionists, the addition of vitamin D to all fluid milk would go a long way toward eliminating the possi-

bility of vitamin D deficiencies, since this vitamin would then be more generally distributed in the medium which furnishes the best sources of those nutrients (calcium and phosphorus) in conjunction with which vitamin D specifically functions.

The cause of demineralization of the skeleton sometimes observed in elderly persons, and known as senile osteoporosis, may be due in part at least to chronically poor food habits and especially to inadequate intakes of calcium, phosphorus, ascorbic acid and vitamin D. It is not certain but that development of this condition may have other underlying causes, such as endocrine readjustments, which accompany other phases of ageing. However, satisfactory intakes of those nutrients known to promote the maintenance of good skeletal structures are certainly to be recommended to aged persons as well as to persons of younger years.

From this short summary of the role of minerals and vitamins in applied nutrition, it is abundantly evident that we are beginning to understand some of the fundamentals of nutritive processes. We can also begin to understand some of the fundamental relationships between ourselves and the great expanse of ocean from whence we came and the plant life from whence we derive sustenance. The science of nutrition, as it gradually develops, has pointed distinctly more toward a better life than toward a longer life. Lest we hold too much hope of an increased life span, I quote here from J. H. Cohausen (*Hermippus Redivivus*): "Of all the wild chimeras which have in all ages haunted the minds of fantastic dreamers, none has taken so great a hold on its votaries as the search for the 'Elixir Vitae' or means of prolonging life beyond its allotted span." Enthusiasts have believed that "by lengthening life, they would confer a priceless boon on the human race: forgetting that it is not the length of the day which makes us love the summer, but the brightness of the sun, the beauty of the flowers, the singing of the birds."

ADDENDUM

Subsequent to preparation of this chapter, an article dealing with the metabolic oxidation of sugar and fat and the relation of these to the citric acid cycle shown in Fig. 5 has been released [Breusch, F. L., *Citric Acid Cycle: "Sugar and Fat-breakdown in Tissue Metabolism," Science*, **97**, 490-492 (1943)]. In view of the fundamental implications contained in this article, it is being cited here for the benefit of readers especially interested in the chemistry of tissue oxidations since there is introduced in this article a possibility of some important departures and extensions of earlier concepts of these reactions.

The Mechanism of Hormone Action

OLIVER KAMM AND D. K. KITCHEN

Research Department, Parke, Davis & Co., Detroit, Mich.

Introduction: Chemical Activators, Vitamins, Hormones and Enzymes

The biological catalysts that control the intricate chemical processes which occur in the animal body are, in the order of increasing complexity, the chemical activators, the vitamins, the hormones, and the enzymes. This chapter will deal in an elementary way with the mechanism of action of the hormones; the mechanism of vitamin and enzyme actions has been treated elsewhere.

All forms of life, including single-celled organisms, are in part under enzymatic control, and even bacteria require certain vitamins and growth factors, especially para-aminobenzoic acid; * but only highly organized forms of life—mammalia, aves, reptilia, amphibia, pisces—require hormones. The vertebrates are listed above in reverse order to their state of development; all possess a full complement of endocrine glands¹—specialized organs for the manufacture, storage, and distribution of hormones.

The term *hormone*, which is derived from a Greek word which literally means “to arouse” or “to stir up,” has suffered abuse in recent years and has been loosely applied to a wide variety of chemical substances. This may be readily appreciated by a review of Starling’s original definition² which was intended to include principles elaborated by cells at one site but which produce a physiologic response in certain cells or structures remotely situated in the body. In its broadest interpretation, such catabolites as carbon dioxide and histamine could be considered as hormones.³

In his review article, *Chemical Regulation and the Hormone Concept*, Huxley⁴ has proposed a classification of active principles which affect growth into (a) local activators and (b) distance activators or hormones. The latter group then is further classified into (1) diffusion hormones and (2) circulating hormones. Goldschmidt⁵ went even further, and referred to the hypothetical masculinizing and feminizing substances which have been postulated to account for the facts of sex in insects, as “intracellular hormones.” “These would thus differ from the ordinary chemo-differentiators of vertebrate embryology in being produced in every cell of the body according to its chromosome constitution, but would resemble them fundamentally in being produced by the same cells on which they exert their specific effect. When, however, the characters concerned are non-sexual, there are of course parallels between vertebrates, insects and other organisms such as plants, for in all these there may exist sharply marked mosaic patches of tissue produced in a heterozygote by the accidental elimination of a chromosome carrying a dominant gene.”⁴

Endocrinologists, however, have limited the term *hormone* to an active principle produced by a specialized tissue, an endocrine or internally secreting gland, which delivers its secretion directly to the blood stream for transportation to other parts of the body where its specific physiologic effects are produced. (This does not imply that hormones do not also diffuse through the tissues.) There is no sound reason why a substance which stimulates plant growth or vegetative reparative processes

* This statement is not intended to imply that para-aminobenzoic acid is a vitamin. Its status, in this respect, is uncertain.

should be regarded as a hormone; such substances either should be termed plant stimulants or plant activators. They are related in a way to compounds occurring in the animal body which will be referred to subsequently as chemical activators.

Chemical activators are compounds of low molecular weight and of simple chemical structure and, in general, are formed at the site of reaction. The primary difficulty in their detection and isolation is due to their occurrence in the tissues in extremely minute amounts. The ones best understood are acetylcholine and adrenine; the latter, referred to also as sympathin, may possibly be identical with the most simple of the hormones, adrenalin. These are referred to subsequently in the section dealing with chemical activators.

The vitamins also are compounds of relatively simple structure; some of them have been synthesized and we can anticipate that ultimately all of them will be identified and synthesized. Fourteen vitamins are now known^{6, 7} and it is believed that two or more still remain to be discovered.

The vitamins occur widely in nature and are obtained by animals in a haphazard manner with their food. They are not destroyed by the digestive processes and are readily absorbed. They are essential to the proper functioning of the animal body, but fortunately an excess does little or no harm; indeed, in some cases ten to a hundred times the amount of a vitamin necessary for natural functional maintenance has proved to be harmless; in fact, beneficial and specific drug effects have been ascribed to such dosage.^{8, 9, 10, 11}

The hormones, on the other hand, are more specific in their mode of action; they are produced within the body itself in exactly the amounts required for normal function and an excess may be as deleterious as a deficiency. Examples of both types of dysfunctions are seen regularly by the endocrinologist in patients displaying hyperthyroidism or hypothyroidism, and hyperinsulinism or hypoinsulinism, while endocrine imbalance secondary to pituitary failure is the basis of the most common of all dyscrinisms. This quantitative distinction between the physiological actions of hormones and vitamins ultimately should throw some light on their respective reaction mechanisms; perhaps the former are primary in type, whereas dysfunctions due to the latter are caused by the absence of complementary factors.

Although much is known about the chemical structure of vitamins and hormones, we have no adequate explanation as to why such structures produce specific physiologic effects and why very slight chemical changes in the active molecules should lead in many cases to complete loss of activity; the lock-and-key analogy may be correct but it discloses no mechanism. There is no question, however, that as our knowledge accumulates, a clearer picture of the mechanism of action will emerge. Most of the references to hormone mechanism in the endocrine literature relate to the physiologic effects produced by the hormones or studies of their metabolic products; but the basic question of *how* the hormones function remains unknown. At this stage, therefore, a certain amount of speculation may be in order, but it should not take the place of continuous laboratory work.

Enzymes are even more complex than either vitamins or hormones; in addition, they are more heat-labile. They appear to act by bringing substances into molecular contact under conditions where chemical changes occur readily. Evidence is available which indicates that some of the vitamins may function as parts of enzyme systems. This is particularly true of some of the B vitamins, but it is probable that the other vitamins and some of the hormones also may be serving primarily as constituents of enzyme systems.

The Endocrine System

The following glands are usually regarded as endocrine structures: anterior pituitary, posterior pituitary, pineal, thyroid, parathyroid, thymus, pancreas, adrenal cortex, adrenal medulla, and the sex glands.

The status of two of the glands in the above list, the pineal and thymus, is uncertain from the standpoint of incretory function, although anatomical alterations in these glands are sometimes noted in such pathological conditions as hypergenitalism and osseous maldevelopment. It must be recognized that no convincing evidence has as yet been produced to ascribe unquestionable endocrine function to these glands. Comparatively, it will be noted that the female possesses an additional gland to those either actual or comparable in the male. This is seen in the case of the ovary, which secretes estrogenic compounds but which in addition contains the corpus luteum, a component part of the ovary which elaborates the hormone progesterone and gives the female gonad a dual performance. In the male the testis is recognized as the origin of the male sex hormones, although a lesser amount of androgens is secreted also by the adrenal cortex. Some workers believe that the prostate may prove to be a gland of internal secretion; however, it remains for further research to present unquestioned evidence upon which such a decision can be based.

We must not confuse the closely related estrogens, androgens and cortical steroids* with multiple hormones such as occur in the anterior and posterior pituitary glands. The latter differ from one another both in chemical and physiologic properties whereas the individuals in a given group of steroidal hormones possess qualitatively the same physiological properties.

In addition to the hormones, or rather groups of hormones, listed above it is recognized that certain active principles (chemical activators) are produced in the upper regions of the intestinal tract. We refer specifically to the principle, *secretin*, which stimulates the flow of pancreatic juice, *cholocystokinin*, the so-called gall-bladder hormone and *enterogastrin*, which influences the flow of gastric juices. These products truly are chemical messengers. They are secreted in one part of the body and control the functions of structures in distant parts of the body; in fact, the word *hormone* was coined by Starling specifically for the product *secretin*. It will be noted, however, that these three activators do not satisfy the full definition for *hormone* as accepted by endocrinologists and as presented above.

An interesting peculiarity of hormone formation may be seen at times in the ability of certain specialized tissues to take over production at certain critical periods in life. This may be illustrated by the characteristic secretion of ovarian hormones by the placenta. During the non-pregnant state, the bulk of estrogenic secretion is maintained by the ovary, a small amount originating in the adrenal cortex. Progesterone is also rhythmically elaborated from the corpus luteum in the non-gravid state. At approximately the end of the fourth month of pregnancy the chorionic elements of the placenta take over the production of estrogens and progesterone, both of which are excreted (the latter in the form of its reduction products) in enormous amounts throughout the remainder of gestation. It is also well known that certain tumor tissues originating within endocrine glands have the ability to secrete hormones in excessive amounts, depending upon the type of neoplasm involved. Such aberrations of growth may take place in either sex at any period of life and during the non-pregnant or pregnant state.

Although there is room for argument regarding the mechanism of hormone action, scientists agree that the enzymes exert their effects through catalytic means. That may be true also of the vitamins.¹² Apparently they act upon a substrate by

* The term *hormomer* is proposed for the multiple active principles which are produced by a given endocrine structure and which are closely related chemically and physiologically. Thus, the six active steroids which have been isolated from suprarenal cortex extracts are hormomers.

A related term *vitamers* has been found useful by workers in the vitamin field. Vitamins D₁, D₂, and D₃ and likewise K₁ and K₂ are vitamers, whereas the various B vitamins, B₁, B₂, etc., are really independent vitamins, each of which corresponds to a series of vitamers, such as B₁ vitamers, B₂ vitamers, biotin vitamers, etc.

forming a temporary adsorption compound, thus producing specific strains upon electronic areas, provided that they correspond to specific electronic areas in the catalyst itself. As a result, specific chemical reactions take place; the adsorption compound then resolves itself (perhaps due to the action of the end-products produced), and the enzyme is regenerated and enabled to exert its catalytic effect upon other molecules. There is considerable evidence that hormones act in a related manner.

An ideal catalyst, even though present only in traces, assists in the chemical conversion of a large amount of material without itself undergoing permanent changes. From this standpoint, and by strict definition, the hormones are *not* ideal catalysts; they undergo chemical changes in the body and are either destroyed or excreted at times in modified form. Extensive research on the metabolism of the hormones is under way in many laboratories; such work is of importance, since undoubtedly it will contribute something to the solution of the problem of how the hormones produce their effects.

Inasmuch as an excessive elaboration of hormones may produce deleterious effects, it is readily apparent that a natural mechanism of hormone destruction is imperative; were such a process not available, one might readily visualize cumulative effects which would in a short time result in impairment of physiologic processes as well as in mutilation of the endocrine system to a point where endocrine salvage would be highly improbable.

A few of the hormones, such as adrenalin, the steroidal sex hormones, and thyroxin have been synthesized,* but the more complex members, such as the peptide and protein types (posterior pituitary, insulin, anterior pituitary and parathyroid hormones) are beyond the scope of synthetic methods now available. There is always the possibility, however, that physiologic activity may reside in an integral part of a complex molecule—the prosthetic group—and that a simpler structure possessing the identical physiologic activity of the hormone might be producible by synthesis.

At the present stage of our knowledge of the endocrine system and its hormones and hormomers, we are likely to overlook the Herculean labors† which have led from one mountain peak to another and have given a glimpse of the foreboding and towering ranges still beckoning to the workers in this field. Extensive and painstaking investigation was required even to prove that certain glands actually *are* endocrine structures. In some instances a detoxifying action was attributed to a gland, and years of research were necessary to prove that the gland actually produces active principles (hormones) which find their way into the circulating blood for transport to distant parts of the body. For years the adrenal cortex and the parathyroids were believed to possess detoxifying properties; instead of contributing a constructive factor to the blood stream they were assumed to destroy toxic factors in the blood as it passed through the glands. An excellent review of that early work will be found in Barker's monumental treatise.¹⁸

After the demonstration that a given gland produces a hormone, and therefore is an endocrine gland, the questions to be asked are: (1) What physiologic effects are produced by the hormone? (2) Upon which tissues do the hormones act?

* The term *synthesis* is used in its broadest sense. Actually the syntheses involved in the production of the steroidal hormones and hormomers are recognized as "partial syntheses." They have been produced by degradation (and resynthesis) of cholesterol and other complex steroids which themselves have not yet yielded to synthesis. On the other hand one estrogen, equilenin, has been produced by total synthesis (Bachmann, W. E., *et al.*, *J. Am. Chem. Soc.* **62**, 824 (1940)).

† The Sixth Labor, the Cleansing of the Augean Stables, is not far removed from the endocrinologist's labor in collecting and isolating hormomer and related compounds from the urine of animals.

(3) What is the mechanism of the actions? The difficulty of answering these questions may be illustrated by referring to the parathyroid glands, as an example.

The Parathyroid Glands

After early goiter operations (thyroidectomy) the symptom-complex known as tetany was at times encountered, and finally it was discovered that tetany was due not to the removal of the thyroid gland itself but to the simultaneous and accidental removal of four minute glands (the parathyroids) which are closely associated with thyroid tissue and usually embedded therein. The symptoms of tetany were associated with the action of toxins, and it was logical to assume that the parathyroids might exert their effect by destroying such toxins. Subsequently, however, it was found that tetany was accompanied by a low blood calcium level and that the administration of calcium salts temporarily relieved the tetany. Finally, the work of Hanson¹⁴ and shortly thereafter of Collip¹⁵ demonstrated that parathyroid glands could be extracted by a special technique (strong acid digestion) to yield an active principle which, when administered to parathyroidectomized animals, raised the blood calcium and relieved the tetany.¹⁶

The work referred to answers at least partially the first of the questions propounded above: What physiological effects are produced by the hormone? We must still determine *where* and *how* the hormone acts; naturally various hypotheses are set up, tested, and discarded or retained on the basis of experiment. Possibly the hormone facilitates absorption of calcium from the intestinal tract; perhaps it prevents calcium loss from the kidney; perhaps it releases calcium from the main calcium depots of the body—the bones; these are just a few of the hypotheses that might be, and actually were, presented. The last-mentioned is accepted at the present time. The next question is: How does the hormone act? This question regarding mechanism is more complex—it may involve, as will be seen, a series of questions. In addition, Nature may have provided *several* mechanisms. In the case of calcium metabolism it is known that vitamin D is involved also. At this stage workers speculated whether vitamin D was merely an intermediate from which the parathyroid hormone is synthesized in the body, as iodine is utilized in the synthesis of the thyroid hormone.

It is known now that the parathyroid hormone and vitamin D have independent and opposite functions although both relate to calcium metabolism. Under normal conditions both calcium deposition and calcium absorption from bone are going on at all times. Such dual (dynamic) control over essential physiological functions is common in the endocrine field and will be referred to again.

But *how* does the hormone exert its effect in maintaining a constant calcium level in the blood? The generally accepted view is that it acts indirectly; its action is on phosphorus metabolism, and the changes in the calcium level are dependent on changes in the metabolism of phosphates.¹⁶ Thus one must ask next, How is the phosphate level controlled? And if the answer is that the kidney is involved, the next question regarding mechanism must be, How does the parathyroid hormone affect the tubules or other parts of the kidneys in producing the final result? The observed facts have been well presented by Albright.¹⁷ "The theory to which I adhere is based on the hypothesis that the hormone affects phosphates in the circulating body fluids in such a way that their excretion in the urine is increased. This would explain the immediate hyperphosphaturia on administration of parathyroid extract and the resulting hypophosphatemia. Furthermore, because of the lowered level of serum phosphorus, it is contended that the serum would be less saturated with respect to calcium phosphate and there would be an increased tendency for calcium phosphate to enter the serum from the gastrointestinal tract or from the bone. This would lead to hypercalcemia, and finally the hypercalcemia would lead to hypercalciuria."¹⁸

The Anterior Pituitary

"The most important endocrine gland is the anterior pituitary. It occupies that exalted position because it controls the other endocrine glands. In popular language it has been called 'the leader of the endocrine orchestra.'"¹⁹

Five anterior pituitary hormones are generally recognized. They are (1) the growth (somatotropic) hormone; (2) the gonadotropic hormone; (3) the thyrotropic hormone; (4) the corticotropic (adrenotropic) hormone; and (5) the luteotropic (lactation) hormone. The growth hormone^{20, 21} seems to be a specific principle essential to general body growth (skeletal, soft tissues and viscera). It can be considered as a general cellular stimulant. The other hormones listed are specific stimulants for individual endocrine glands, as their names indicate.

Although claims have been advanced in favor of the existence of two gonadotropic hormones, a follicle-stimulating and a luteinizing hormone,^{22, 23, 24, 25} the existence of the latter may be questioned. The effect on the corpus luteum may well be due to the presence of the growth and lactogenic hormones; indeed the recent work of Astwood²⁶ has shown that the principle previously designated as the anterior pituitary lactogenic hormone is a luteotropic factor. Its function is to stimulate and maintain the corpus luteum; its effect in causing lactation in animals under certain conditions may be merely a corollary of its luteotropic effect. Although no adequate proof has been submitted in favor of the existence of an anterior pituitary parathyroid-stimulating hormone, a posterior pituitary-stimulating hormone and an adrenal medulla-stimulating hormone, there is no reason why the "endocrine leader" should direct five members of the "orchestra" and not the others. The work of Houssay²⁷ has definitely shown that the anterior pituitary exerts a striking effect on carbohydrate metabolism. He showed that although the surgical removal of the pancreas alone will cause diabetes, if the anterior lobe of the pituitary is also removed the animal has no glycosuria and stays in reasonable health. It is clear, therefore, that the anterior pituitary secretes a hormone with an opposite effect on sugar metabolism to that of insulin, and that we have here another instance of dual control of a metabolic process.

Mechanism of Action of Anterior Pituitary Hormones

We are concerned primarily not with the number of these multiple hormones or their physiological effects, but rather with the mechanism whereby a single gland can produce profound effects on every part of the body. It may appear strange that a gland with only two types of secreting cells²⁸ can produce five (and perhaps eight or more) separate hormones. That fact, however, need not disturb us, since there seems to be no end to the multitudinous reactions carried on in the liver with the aid of only one type of cell.²⁹ Possibly the growth hormone is produced in one type of cell and all the glandulo-tropic hormones in the other.

A principle that might be accepted as a working hypothesis is this: When multiple hormones are produced by an individual gland they will prove to be closely related in chemical structure. One would not expect a given manufacturing plant to produce threshing machines and microscopes with the same equipment. In the case of the posterior pituitary gland where multiple hormones were first demonstrated, it was found that the two principles were both sulfur-containing peptide-like compounds of approximately the same molecular weight.³⁰ Similarly, all the anterior pituitary hormones are protein-like in nature. That they are released directly into the circulation as the blood passes through the pituitary is more than an assumption, since Friedgood recently has supplied objective evidence.³¹ Once in the circulation, hormones pass successively through the various endocrine glands, each of which has the power of attracting one of them. Thus the thyroid retains the thyrotropic hormone; the gonad, the gonad-stimulating hormones; the adrenal cortex the adrenotropic hormone; etc. There is only one reasonable mechanism by

which such a result can be explained, namely, adsorption of the protein-like hormone on a protein constituent in the gland. This, after all, is analogous to chromatographic adsorption; similar methods are being used in biochemical laboratories to separate the active principles from crude extracts containing multiple hormones and multiple B vitamins.

The endocrine gland can be considered as a manufacturing plant and the glandotropic hormone as the specialized machinery that is needed for the manufacture of the true hormone. Although the next step in the mechanism needs clarification, it obviously is catalytic, the adsorption compound acting as an enzyme to convert suitable intermediate compounds into the final hormone. In the case of the steroidal hormones (male, female, and adrenal cortical) the intermediate either is cholesterol or simpler intermediates produced in the liver. The evidence in favor of the cholesterol theory of hormonogenesis is almost overpowering. There are 256 possible optical isomers of cholesterol, only one of which occurs in the body. It is observed, however, that in every instance the steroidal hormone produced by a gland corresponds in structure to the one specific cholesterol found in the animal body.

One other step in the hormone mechanism must be mentioned here. After the true hormone has been synthesized and is poured into the blood stream, it in turn checks the activity of the pituitary and thus prevents the development of a vicious cycle. Hormones introduced extraneously also produce such effects; indeed, that is the basis for some of their clinical uses.

Adrenalin and Chemical Activators

The mechanism of the action of adrenalin is better understood than that of any of the other hormones because it is simple; its effect is distinctly adrenergic. Adrenalin acts directly on the tissue cells as a chemical activator, and such well known pharmacological effects as vasoconstriction, acceleration of the heart, dilatation of the pupil, inhibition of tracheal and bronchial musculature, etc. are thus more readily understood.

Further consideration of the manner in which hormones exert their effects should logically be prefaced by a presentation of the known facts regarding autonomic function,³² and such knowledge is a prerequisite for some of our speculations to be deduced from our fragmentary information. Definite evidence has been accumulated indicating that the cytoneural junction is the scene of elaboration of chemical substances which affect cellular reactivity following a nervous impulse. It has long been recognized that injections of adrenalin produce effects in most instances identical with those elicited by electrical stimulation of the sympathetic nerves. It is now postulated that this effect of sympathetic stimulation is due to the formation of either adrenalin or a chemical substance closely related to adrenalin at the effector terminal of the preganglionic neuron. Inasmuch as this compound has never been isolated in crystalline form, and since adrenalin may exhibit both excitatory and inhibitory effects, this substance has been designated by Cannon³³ by the convenient term *sympathin*, reserving the terms sympathin E and sympathin I for the effects which either are excitatory or inhibitory in nature.

Since functionally the sympathetic and para-sympathetic nervous systems are antagonistic, it would seem reasonable to postulate the elaboration of a pharmacodynamically opposite substance from the distal terminals of the first and second para-sympathetic neurons. Such a substance actually has been localized after para-sympathetic nerve stimulation and identified chemically as acetylcholine. Investigations conducted by Dale, Loewi, and others over a period of years lend credence to such a concept.³⁸

An explanation of the transitory effect of these chemical substances following a single nerve impulse has been shown, in the case of acetylcholine, to be due to the hydrolytic effect of an ever-present enzyme known as cholinesterase; no similar

enzyme has been demonstrated which is responsible for immediately nullifying the sympathin effect. Green and Richter³⁴ have emphasized the readiness with which adrenalin is auto-oxidizable *in vitro*. On the basis of this fact, they point out that the assumption is often made that such a process is responsible for the destruction of adrenalin *in vivo*. They draw attention to the fact, however, that the tissues contain an inhibitor which is very efficient in protecting adrenalin from auto-oxidation, citing the work of Wiltshire,³⁵ Welch,³⁶ and Heard and Welch.³⁷

Green and Richter have suggested a mechanism by which the sympathin effect might be nullified in a manner similar to the destruction of acetylcholine by the choline esterase system. They present evidence to show that adrenalin is rapidly oxidized by cytochrome and by the indophenol oxidase-cytochrome system. The resulting oxidation product is known to be adrenochrome, which is an active carrier of oxygen but is not adrenergic. Since this indophenol oxidase-cytochrome system is known to be present in most animal tissues, they suggest that the property of inactivation from this system might account for the transitory sympathin effect. These workers also point out that the sympathomimetic drugs which are most rapidly destroyed *in vivo* prove to be the most rapidly oxidized by the indophenol oxidase-cytochrome system.

Dale³⁸ has suggested that chemically these effects of sympathetic and para-sympathetic nerve stimulation should be designated either as adrenergic or cholinergic, depending upon whether the sympathetic or para-sympathetic system is being stimulated; thus, pilocarpine is distinctly cholinergic in effect, whereas ephedrine obviously is adrenergic. Parker³⁹ has also contributed to our knowledge of these neurohumeral substances.

The Sex Hormones

While the above information has enabled investigators to explain some of the effects produced by hormone-like substances, the mechanisms of most of the known end-points of hormonal influence are still obscure. Actual change in tissue morphology is one of the most important functions of the steroidal hormones. Hyperplasia of accessory sex organs in both sexes is a well known process which occurs concomitantly with the utilization of estrogenic or androgenic hormones.* How can the reasons for such tissue growth be postulated? Shall the presence be assumed of highly specific chemical stimulators, perhaps intracellular in location, which are activated by these steroids and which account for cellular mitosis? Such a viewpoint at this time must be considered purely hypothetical.

On the other hand, how can the actual inhibition of cellular growth and tissue regression be explained—a phenomenon which may be easily demonstrated in the average test object following the administration of some of these same steroids? Pituitary inhibition following large injections of estrogenic substance may be cited as an example. The presence of intracellular growth factors which operate locally and by diffusion has been suggested, and they have been erroneously referred to as hormones. It might logically be assumed that the causes of cellular growth or changes in tissue morphology are intimately connected with the cause of life itself. These changes in anatomical structure are the most obvious and important end-points of estrogenic utilization, and these well-known effects apply primarily to the utero-vaginal tract and certain elements of the breast.

From the above facts, it is obvious that there is no explanation for the exact mechanism responsible for this growth; but in connection with known facts concerning autonomic function, striking evidence is available which seems to clarify the mode of action of estrogenic substances on some portions of the vascular tree. Reynolds,⁴⁰ working with rabbits in a well controlled experiment, has shown that

* Cancer of the prostate is now being successfully treated by administration of estrogens (estrone, stilbestrol) or the removal of androgens (by castration). J. A.

the endometrial and myometrial hyperemia which follows injections of estrogenic hormone is due to an increase in tissue acetylcholine. In untreated controls the acetylcholine content was found to be very low, and he arrived at the conclusion that these estrogenic substances are strictly cholinergic in nature, accounting for the vasodilatation and increase in muscular activity. A later study by Reynolds and Foster,⁴¹ however, is somewhat confusing, for by the same experimental approach they showed that injections of stilbestrol, although highly estrogenic, did not significantly alter the acetylcholine content of the uterus even when high dosages were used. Inasmuch as stilbestrol is a member of a different chemical group, the stilbenes, it is possible that only estrogens possessing a steroidal structure will exhibit cholinergic gradients.

Water retention in some tissues, particularly the skin, following estrogens may be accounted for by an increase in capillary permeability due to this cholinergic effect of the estrogens; but changes in calcium metabolism following estrogens are not readily explained. The increased calcium deposition in cancellous* bone following the administration of estrogens in some experimental animals is well known, but the cause for this derangement still remains unknown.

The mode of action involved in the inhibition or stimulation of the anterior lobe of the pituitary by estrogens likewise is unexplainable; these phenomena may be associated with cholinergic stimulation of some of the secreting cells of the gland, which would require a highly specialized mechanism.

Progesterone physiologically is responsible for secretory changes in the cells of the endometrial glands, and perhaps this effect is due to cholinergic stimulation. Although such has not been proved, it is assumed that progesterone is cholinergic and thereby secretory to the endometrial glands.

Steroids possessing androgenic activity are similar to the estrogens in that their end-points are characterized primarily by their effects on tissue growth; these male sex hormones are responsible for growth and physiologic development of the secondary sex characteristics, and hyperemia of these organs may be explained on a similar basis to that offered for the estrogens, namely, cholinergic effects.

Hormones of the Adrenal Cortex

The hormones of the cortex exert their effects in three spheres: first, the salt and water balance of the body, second, the carbohydrate metabolism, and third, the sexual "make-up," particularly the secondary sex attributes.

Of the 24 steroids^{42, 43, 44, 45} which are unique constituents of the adrenal cortex, six are known to have the basic cortical action, namely that of maintaining life in an adrenalectomized animal. They are corticosterone, 11-dehydrocorticosterone, 17-hydroxycorticosterone, and 17-hydroxy-desoxycorticosterone. Of the remaining 16, three have masculinizing activity of varying degree; adrenosterone, 11-hydroxy-isoandrosterone and 17-hydroxy-progesterone. It should also be mentioned that the adrenal cortex has yielded progesterone and estrone.

The actual mechanics of how the cortex hormones influence the salt and water balance is obscure, but the bulk of the evidence indicates that they may act by influencing the specific reabsorption of sodium from the glomerular filtrate as it traverses the ascending loop of the kidney nephron. In the absence of the cortex hormones, sodium and water are thus lost to the body and the vicious cycle of dehydration and circulatory collapse is initiated. That the mere withdrawal of sodium and water is not the really basic effect is evidenced by the fact that clinical improvement can be effected without change in the salt or water content of the body. The other changes in the blood and tissues, such as the blood levels of potassium, chloride, etc., can be traced to the dehydration. There has been a great deal of speculation concerning the effect of the hormones on capillary permeability, but the careful work

* Of a reticular, spongy, or lattice-like structure.

of Muntwyler^{46, 47} and his associates demonstrates that the Donnan equilibrium for semi-permeable membranes is maintained in the deficient animal (dog), making any large change in the permeability characteristics of the cellular membranes appear improbable. That the mere loss of salt itself is not the lethal factor is evidenced by the fact that interrenalectomy in the shark is fatal, even though it is maintained in sea water.

The cortex hormones have a profound effect on carbohydrate metabolism, but here again nothing is really known as to how they act. They are concerned primarily with the maintenance of the liver glycogen reserve, that is, gluconeogenesis, and even in this there is great variability in the different species, the carbohydrate disturbance being much more pronounced in the rat than in the dog. Influence on carbohydrate metabolism appears to be related to the structural feature of an oxygen atom on the eleven carbon atom of the steroid skeleton. The muscular fatigue which is a cardinal feature of adrenal insufficiency is perhaps related to the faulty carbohydrate metabolism, but it may be equally referable to the disturbance in the salt and water balance. In fact the cortex hormones may be the key to the problem of the relationship of carbohydrate metabolism to the salt and water balance.

In the sexual sphere the adrenal cortex probably acts in conjunction with the sex glands. An overactivity of the cortex can cause either masculinization or feminization. Presumably these end effects are obtained by mechanisms common to the sex hormones themselves, and represent merely an excessive secretion of sex active compounds from the cortex.

The Action of Insulin

Many workers have offered individual concepts to explain the physiologic state which occurs on removal of the pancreas and the symptoms seen in diabetes mellitus. A concise review of the subject has been set forth by Cameron.⁴⁸ The two principal theories to explain this state of hypo-insulinism are known as (a) the non-utilization theory and (b) the overproduction theory. Adherents to the former believe that in the absence of insulin the capacity of tissues to metabolize glucose is nearly or completely lost. There is a resulting increased protein and defective fat metabolism from this inability to convert glucose into its end products. This failure of glucose metabolism results in the characteristic hyperglycemia and glycosuria. Another theory explains that hyperglycemia occurs as a result of over-production of glucose in the liver from noncarbohydrate sources such as protein and fat. Hyperglycemia and glycosuria, according to such a concept, are not due to failure of utilization, but to glucose over-production. It may be seen from the foregoing that an explanation of insulin action will vary somewhat, depending on which of the two theories is accepted, but in general there seems to be adequate proof that the following functions may be attributed to insulin. Insulin evidently increases the *rate* at which glucose is converted to glycogen in the muscles and other tissues. Although insulin is probably not specific in this regard, it has been shown by Gemmill⁴⁹ to act *in vitro* in muscle tissue cultures.

Insulin prevents loss of liver glycogen probably because of its inhibitory effect on hepatic glycogenolysis caused by adrenal hormones. Insulin also exerts a certain amount of regulation of oxidation in tissues, that is, it plays the role of arbitrator as to relative amounts of carbohydrate, fat and protein oxidized. Insulin almost certainly decreases the rate of gluconeogenesis from protein. It also prevents formation of ketone bodies from fats. The latter two actions occur in the liver. Insulin both anatomically and functionally prevents and repairs damage to islets caused by anterior pituitary extracts.⁵⁰ There is no clear-cut evidence that insulin influences oxidative mechanisms either directly on metabolites or indirectly on enzyme systems involved in oxidation.

The relative importance in carbohydrate metabolism of the functions of insulin

and of non-pancreatic factors such as the influence of the pituitary, adrenal and thyroid is highly controversial.

The Posterior Pituitary and Water Metabolism

Several of the hormones exert a profound effect on metabolism. Thus the thyroid hormone and the hormoner, thyroxin, affect protein metabolism, insulin controls sugar metabolism, and the parathyroid hormone calcium and phosphate metabolism. Even the utilization of water is under hormonal control—it is the main function of one of the hormones of the posterior lobe of the pituitary gland. The amount of water that we imbibe may be under our own control, but what happens to it after absorption—whether it is promptly eliminated or whether it is retained and stored in certain tissues—is partly under the control of the antidiuretic hormone of the posterior pituitary.

As has been indicated in several of the preceding sections, various processes occurring in the body are under the control of *several* different hormones. Enzymes usually control equilibrium reactions; hormones on the other hand, are absolute monarchs—they control processes which are irreversible. Nature, therefore, has not trusted these basic processes of life each to one individual hormone; it has instituted a system of checks and balances—usually several hormones are concerned in controlling a given mechanism; even vitamins have a part in this democratic system.

It has been shown above that the parathyroid, in cooperation with vitamin D, controls calcium metabolism and that the pancreas and the anterior pituitary are concerned (and that both are major factors) in the control of carbohydrate metabolism; however, even this dual control is not adequate—some powers have been relegated also to the adrenal cortex. One of the functions, perhaps the most important, of the adrenal cortex is to assist in the control of carbohydrate metabolism. It is not surprising, therefore, that the mechanism of action in relation to sugar metabolism still is confused. Similarly, water metabolism is too important a matter to be left to the control of one gland; in addition to the posterior pituitary, one of the hormones of the anterior pituitary, and incidentally one not yet effectively extracted and concentrated, is concerned with water metabolism. Moreover, certain hormones of the adrenal cortex influence water metabolism profoundly, and secondary effects are exerted by the thyroid and the pancreas. Any gland (or hormone) concerned with the metabolism of large molecules and the production from them of compounds of low molecular weight which exert a considerable effect on osmotic pressure in the tissues, will affect water metabolism.

A striking demonstration of the dual control of water metabolism of the posterior and anterior pituitary glands can be made by surgical means. If the posterior pituitary is removed, a condition of diabetes insipidus is produced; an excessive loss of water occurs and the animal suffers from extreme thirst and consumes an enormous amount of water. A condition corresponding to this is met occasionally in medical practice—not necessarily as a result of surgery—although fortunately it is rare; only approximately a thousand patients in our 120 million population suffer in an extreme way from such a defect. Although the condition is very inconvenient, it is not fatal or even dangerous. Fortunately, it is controlled definitely by administration either of posterior lobe extracts or of the antidiuretic hormone "Pitressin." A striking phenomenon in connection with diabetes insipidus is the fact that the kidney effectively conserves (reabsorbs) needed constituents and the urine excreted resembles distilled water. The insipid taste of distilled water in contrast to that of ordinary drinking water ("hard" water) is responsible for the medical term, diabetes insipidus. Unfortunately no reference can be located to the observation of the physician who first tasted the urine of such patients and found it, in contrast to that from those suffering from diabetes mellitus, to be insipid. Diabetes mellitus, on the other hand, is characterized by the elimination of an appreciable amount of sugar. Such urine

tastes like honey; the presence of sugar was noted in Claude Bernard's laboratory, where it was observed that flies were attracted by urine excreted by pancreatectomized dogs. However, nearly three centuries ago Thomas Willis observed such urine to be "wonderfully sweet, as if imbued with honey or sugar."⁵¹

After diabetes insipidus has been produced in an experimental animal by surgical removal of the posterior lobe, a second operation—the removal of the anterior lobe—corrects the condition. The experiment^{52, 53} demonstrates that the anterior lobe also affects water metabolism and probably produces a hormone which effectively balances the water-metabolizing hormone of the posterior lobe.

We are concerned here with the mechanism whereby the posterior lobe hormone produces its effect. In this case, fortunately, definite theories and facts can be presented.⁵⁴

The posterior pituitary is the first gland in which the presence of multiple hormones was demonstrated⁵⁵—a pressor-antidiuretic hormone and an oxytocic hormone. Although some claims have been made to the effect that the pressor effect is due to the presence of a separate factor,⁵⁶ all the work done in Kamm's laboratory* indicates that a single hormone is involved. This is not an unusual situation; even from as simple a hormone as adrenalin we note various physiologic responses—effects on blood pressure, on the bronchioles, on carbohydrate metabolism, etc. Why should the antidiuretic hormone of the posterior pituitary be an exception to this basic principle?

The possibility that man has descended from sea-living animals is supported by the fact that the composition of his blood is related chemically to that of sea water. Moreover, it is an axiom of physiology that the composition of the blood is constant—that constancy is maintained partly by the glomeruli and tubules of the kidney. Enormous quantities of water are metabolized—possibly 40,000 cc per day—and yet man needs to drink and obtain in his food only approximately a liter of water per day. The explanation is that water is reabsorbed by the tubules of the kidney and is utilized again and again. An estimate of the quantities of water involved in life processes in an average case is illustrated in Table 1.⁵⁷

Table 1. Intermediate Water Exchange (Human Subject)

| Secretion | Amount (cc.) |
|---------------------------------------|--------------|
| Saliva | 1500-(5000?) |
| Gastric juice | 2000- 3000 |
| Pancreatic juice | 500- 800 |
| Bile | 300- 500 |
| Succus entericus | 2000- 3000 |
| Kidney reabsorption | 10000- ? |
| <hr/> | |
| Average water intake (including food) | 1700 cc |
| Urine | 800 |
| Feces | 200 |
| Average Excretion | |
| Respiratory Tract and Skin | 700 |
| Total | 1700 cc |

The facts concerned in water metabolism are important and obvious, but it seems desirable to seek the mechanism whereby the antidiuretic-pressor hormone of the posterior pituitary produces its striking effect. If that can be found, a clew may be available also as to how other endocrine principles exert their effect on water metabolism. It does not follow, however, that the reaction mechanisms are identical; in fact Nature's safeguard lies not only in multiple control of the process but

* The work is being assembled for publication.

in varying mechanisms. The posterior pituitary theory of mechanism is presented herewith.

It is well known that body fluids are rich in sodium and poor in potassium. The latter ion is essential for the heart mechanism, but an excess is fatal. On the other hand, body cells are rich in potassium and low in sodium; for example, if the potassium in the red blood cells were released even partially, death would result. Fortunately, Nature has guarded against such an emergency by providing the red cell (and other cells also) with a specialized (impermeable) membrane which prevents sodium ions from diffusing into the cell and potassium ions from diffusing out.⁵⁸

Many theories have been advanced to explain the effect of posterior pituitary extracts upon water metabolism, since it must be intimately associated with salt metabolism. Such theories, or rather hypotheses, cannot be reviewed here; it is sufficient to state that the most common one is to ascribe the effect to a kidney mechanism. If the kidney controls the sodium and potassium levels of the blood (and of the anions as well), then the blood and lymph levels are controlled by the same mechanism, since the capillaries are truly semi-permeable membranes such as the chemist deals with in his laboratory, and osmotic relations will furnish the rest of the picture. Such a theory, however, overlooks the specialized membrane possessed by most of the body cells.

A more logical mechanism appears to be the following: The antidiuretic hormone acts upon the specialized membranes of the body cells (those of the muscles especially) and modifies them *slightly* in the direction of true dialyzing membranes. The effect may be due mainly to changing the type of emulsion or colloid present in the cell membrane. This effect is mediated through a nervous control—that is why the red cells, freely floating in the blood, are not influenced. As a result of the change in the distribution of electrolytes, a change in water concentration will follow. A relatively minute change in salt content of the cell can effect an enormous change in water transport. The effect of the posterior pituitary antidiuretic hormone, therefore, is to hydrate tissue cells. The anterior pituitary probably exerts a similar effect, but in the opposite direction. The net result following a dose of vasopressin ("Pitressin") is to cause a flow of water to the tissue cells (provided an excess of water is available for transportation) and to cause increased salt (especially potassium) excretion by the kidney. Long before this theory of reaction mechanism was presented, Stehle⁵⁹ had shown that large doses of posterior lobe extract increased greatly the excretion of potassium, thus substantiating the theory.

Conclusion

In the chapter entitled "Catalysis as a Biological Factor," the statement is made that "though much is known as to the *effects* produced by hormones, little is known as to the basic *mechanism* whereby these effects are produced." Possibly the survey presented in the present chapter substantiates that conclusion. It is believed, however, in spite of the lack of progress that has been made up to this time, that research in the field of hormone mechanisms offers a fruitful range of work. At a recent Hormone Symposium,⁶⁰ practically nothing was mentioned concerning this aspect of endocrinology. It is predicted, however, that in the future, hormone symposia will be held in which most of the papers will contribute to this important field. Possibly, as Jeans⁶¹ points out, from the nature of things science can never attain to a knowledge of the realities of the world. He states, "Our sense-organs form a sort of screen on which nature's lantern is forever projecting pictures; we can study these pictures, but can never pass behind the screen to see how the lantern works. And as the sequence of pictures thrown on the screen is all that we can ever know or study, a set of laws that links the pictures together in a perfect systematic order is the most that science can provide, or can properly be asked to provide."

As has been pointed out, an investigation of the mechanism of hormone action aims to answer the question How?; perhaps we can never answer the question Why? Perhaps we can never look behind the screen and obtain a glimpse of the lantern, but still there is no reason to be discouraged. Great discoveries await workers in this field and at times, no doubt, enthusiastic investigators will even attempt to invade the field that Jeans tells us is beyond the screen. They should not be discouraged.

The Molecular Organization of Visual Processes *

GEORGE WALD

Biological Laboratories, Harvard University, Cambridge, Mass.

The purpose of this paper is to discuss briefly certain macromolecular and micro-anatomical relations which govern the photoreceptor processes in vision. The further chemistry and phylogeny of these processes have recently been reviewed elsewhere (Hecht, 1942; Wald, 1942, 1943); detailed references to the literature will be found in these papers.

The Anatomy of Photoreception

The eye contains three tissues, each of which makes specific contributions to visual metabolism. Proceeding from the interior outward these are (1) the retina proper, consisting in order of a layer of ganglion cells from which spring the fibers of the optic nerve, a layer of communicating neurones, and the photoreceptor layer; (2) the single-layered pigment epithelium; and (3) the choroid, one of the most highly vascular tissues in the body (Fig. 1 A).

Most vertebrate retinas contain two kinds of light receptors: rods, ordinarily concerned with vision in dim light, and in man conveying only neutral gray sensations; and cones, the organs of vision in bright light, detail and color vision. Both cells bear at their extremities dense structures, their so-called outer limbs, to the shape of which they owe their names and to whose photosensitive pigments they owe their reactivity to light.

Outside the class of mammals, few retinas have a blood supply of their own. Even in mammalian retinas the circulation is sparse and in certain areas entirely absent, as in the human fovea, the region of most acute vision. The retina depends quite generally, therefore, upon the choroidal circulation for the supply and removal of metabolites; and these must pass in transit through the intervening pigment epithelium.

The latter is a true retinal layer, derived embryonically from the proximal wall of the ectodermal optic cup, just as the retina proper is developed from its distal portion. Normally both tissues lie in intimate contact, though joined only at the rim of the pupil. Franz Boll (1877) in the paper which announced his discovery of rhodopsin, the photosensitive pigment of the rods, expressed the conviction that the rods and the cells of the pigment epithelium constitute a physiological unit. In the frog, as in other cold-blooded animals, light causes the granules of epithelial pigment to stream into long protoplasmic filaments which project among the outer limbs of the rods and cones; in darkness the granules retire to the basal portions of the epithelial cells. In the light also the retina proper adheres firmly to the pigment epithelium, while in the dark these tissues lie in loose contact. The pigment epithelium of the frog contains golden oil droplets, in the pigment of which Boll thought he had found the precursor of rhodopsin. This shrewd guess narrowly missed its mark; it is now clear that this pigment, the carotenoid xanthophyll or lutein ($C_{40}H_{54}(OH)_2$), does not participate in the rhodopsin system (Wald, 1935-36a, b). Shortly afterward, however, Kühne (1878) was led by observations mentioned below to ascribe to the pigment epithelium a central role in the synthesis of rhodopsin.

* The original researches described in this paper have been supported in part by the Milton Fund of Harvard University, and the Josiah Macy, Jr. Foundation of New York.

FIGURE 1—A. Arrangement of cell layers in the interior of the eye. The rods and cones, connector neurones, ganglion cells and optic fibres constitute the retina proper. The pigment epithelium, though anatomically distinct, is a true retinal layer.

B. Microstructure of the outer limb of a rod. Within a sheath of neurokeratin are alternate layers of protein and lipids. Rod-shaped protein molecules are oriented transversely; long-chain lipid molecules are principally oriented longitudinally. Many of the latter have their polar groups (shown as small black circles) directed toward or bound to the protein layers. The thickness of both types of layers is here greatly exaggerated; it is actually below the limits of visual resolution (about $200\text{ m}\mu$) and probably of the order of $\frac{1}{25}$ – $\frac{1}{50}$ the total width of the rod. (Modified from Schmidt, 1938.)

C. Dichroism of rhodopsin in the dark adapted rod. In light polarized in a plane parallel to the long axis of the rod it is colorless; in the perpendicular plane it is red. In cross-section the rod appears red in all planes of polarization, showing that in this dimension the molecules of rhodopsin are oriented at random. (Modified from Schmidt 1938.)

The outer limb of a rod or cone is a complex structure. It is completely enclosed in a sheath of relatively inert protein identified by Kühne (1878b, p. 40) as neurokeratin. Its interior normally looks entirely homogeneous even under high magnification. But when rods are bathed in water or acid or alkaline solutions, the outer limbs lengthen and attenuate, and simultaneously are divided by cross-striations into the appearance of cylinders filled with discs. The basis of this behavior is a microstructure of alternate layers of protein and of a mixture of lipids—mainly phosphatides—resembling that found in nerve myelin. The swelling of these layers in certain media makes this construction visible. The molecules of both protein and lipids are oriented to a degree, and the optical properties of the outer limb in polarized light have their source largely in this factor (Fig. 1 B) (Schmidt, 1938).

The outer limb is positively birefringent, its single optic axis lying parallel to its long dimension. This property is the resultant of a number of separable components: (a) Strong positive intrinsic birefringence (*Eigendoppelbrechung*) originating in the lipid layers, in which long carbon chains appear to be oriented parallel to the length of the rod; (b) weak positive intrinsic birefringence due to the protein layers, which appear to contain rod-shaped molecules oriented perpendicularly to the length of the rod; and (c) negative structure birefringence (*Formdoppelbrechung*) due to the alternation of these layers which differ in refractive index; that of the

protein is extraordinarily high, about 1.60, while that of the lipids is probably comparable with nerve myelin, about 1.50. It is the transverse orientation of its protein molecules that causes the rod to lengthen and constrict when treated with acids, alkalis or heat. On such treatment most protein fibrils, the molecules of which lie longitudinally, thicken and contract.

It is important to note that the rod, viewed end-on, is isotropic. Its molecules apparently are oriented at random in the cross-sectional plane. The way in which photosensitive pigments enter into this structure is not wholly clear. The rod photopigment rhodopsin, however, is known to be oriented within the rod, since it is dichroic in polarized light. Dark adapted rods lying perpendicular to the plane of polarization look pink, those parallel to this plane look colorless. In cross-section the rod looks pink always, showing that in this plane rhodopsin shares with the total structure of the outer limb a random orientation (Fig. 1 C). Light travelling down the long axis of the rod—its normal direction of penetration in the eye—encounters only isotropic structures. It is for this reason that plane-polarized light has almost no special properties as a visual stimulus.

Retinal Photopigments

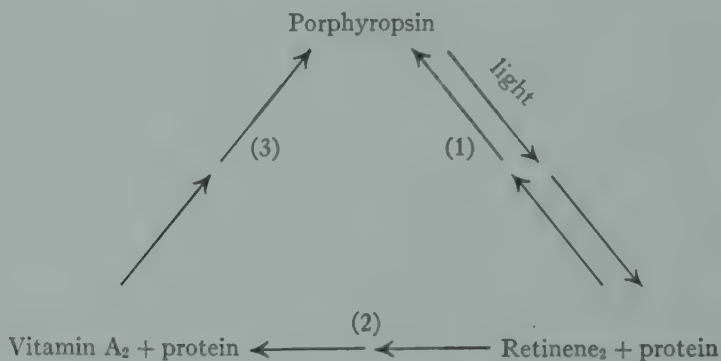

Three retinal photopigments are now known: rhodopsin and porphyropsin in rods, and iodopsin in certain cones. The rod pigments—and probably iodopsin also—represent a conjunction of protein and lipid elements reminiscent of the total structure of the outer limb. They are conjugated proteins which owe their color to the possession of carotenoid prosthetic groups—groups belonging to the class of fat-soluble animal and plant pigments which includes the vitamins A. This composition lends the photopigments a dual character. Like all proteins they have colloidal dimensions, intricate and highly perishable structures, and some tendency toward solution in water. Their carotenoid residues, however, are highly water-repellent, and beyond markedly affecting their solubility and optical properties, involve them in a series of special external relations—the dietary supply and general metabolism of the carotenoids and vitamins A, none of which can be synthesized *de novo* in the vertebrate body.

Rhodopsin is a rose-colored pigment found in the rods of marine fishes, certain amphibia, birds and mammals (Wald, 1942, 1943). When exposed to light it bleaches to orange or yellow products (Kühne's "visual yellow") which yield all their color to neutral fat solvents. The pigment so extracted is the yellow carotenoid retinene₁. Following irradiation of dark-adapted retinas, the initial color due to retinene₁ or its immediate precursors slowly fades, a visible indication of the conversion of these substances to the colorless vitamin A₁ ($C_{20}H_{20}OH$). This is an ordinary thermal reaction. It predominates even in darkness, though here in addition a little rhodopsin is also regenerated. In isolated retinas vitamin A₁ and protein are the final products of bleaching. But in the intact eye these substances in turn are resynthesized to rhodopsin. The system as a whole therefore constitutes a cycle of the form (Wald, 1935-36a, b):

Isolation of the retina cuts the cycle at (3). Extraction of rhodopsin into solution virtually eliminates also reactions (1) and (2), leaving only the bleaching of rhodopsin to a mixture of retinene₁ and colorless protein.*

Porphyropsin is a purple photopigment found in the rods of fresh-water fishes, cyclostomes and certain amphibia. It is linked genetically throughout the vertebrate phylum with the capacity for fresh-water existence, particularly with a fresh-water embryonic history (Wald, 1942, 1943). Its general chemical behavior and the form of its retinal cycle are identical with those of rhodopsin. The absorption spectrum of each component of the porphyropsin system, however, is displaced 20-30 m μ toward the red from that of its analog in the rhodopsin cycle. The basis of this difference is the presence in the porphyropsin system of new carotenoids, called at present retinene₂ and vitamin A₂. It therefore has the composition (Wald, 1937a, 1938-39b):

Just as in the rhodopsin system, isolation of the retina cuts this cycle at (3); and extraction of porphyropsin eliminates also reactions (1) and (2).

The structure of vitamin A₂ is not known. Within the class of carotenoids, however, a shift of spectrum 20-30 m μ toward the red is known to accompany the addition to the polyene chain of one conjugated double bond. Such an added double bond appears to be the sole difference between the porphyropsin and rhodopsin systems. This small change explains not only the constant spectral displacement which involves all members of both cycles, but their extraordinary parallelism in behavior, since this change should only slightly affect their chemical properties.

Little is yet known of iodopsin (Wald, 1937b; Chase, 1938). Its idiosyncracies in solubility and its optical properties suggest close chemical relationship to the photopigments of the rods. Its spectrum is shifted some 40 m μ toward the red from that of porphyropsin, and by analogy one might suppose that it contains a still longer conjugated polyene group. In human night-blindness, due to lack of vitamin A, the threshold of cone vision rises with that of the rods, and returns simultaneously to normal on administration of vitamin A₁ (Haig, Hecht and Patek, 1938; Wald, Jeghers and Arminio, 1938). It is probable, therefore, that the cone photopigments are closely related to rhodopsin in structure, and are similarly derived from vitamin A or a comparable substance.

It is well known that the sensitivity of human vision in various regions of the spectrum is displaced toward the red as one passes from dim to bright light, *i.e.*, from rod to cone function. This is the Purkinje shift. Since the *shape* of the spectral sensitivity curve is almost identical in dim and bright light, Hecht and Williams (1922-23) suggested that its difference in *position* in the spectrum might have a purely structural explanation: that cones, like rods, may contain rhodopsin, but that, possibly because of the higher refractivity of the outer limbs of the cones, its spectrum

* Under certain conditions a small residue of reaction (1) is temporarily retained in solutions of rhodopsin (Ewald and Kühne, 1878, p. 262; Hecht, Chase, Shlaer and Haig, 1936).

in these organs is shifted toward the red in accordance with Kundt's rule. Hecht later discarded this view. It is now clear that rods and cones possess chemically distinct photopigments; and in the only retina in which this matter has been explored—that of the chicken—the optical properties of rhodopsin and iodopsin in solution account directly for the Purkinje shift (Wald, 1937b).

Form and Function

Within the outer limbs of the rods and cones the photopigments must form part of the protein layers, though possibly they are oriented so that their carotenoid groups project into the lipoidal interstices. Such an arrangement would aid the passage into and out of the retina of the vitamins A, a process prominent in the operation of the rhodopsin cycle. It has been observed that frog retinas light-adapted *in vivo* lose about 2%-5% of their vitamin A₁. Originally this datum was taken to mean that vitamin A₁ is destroyed in the visual processes (Wald, 1935-36a). It appears instead, however, to be direct evidence that, as the concentration of retinal vitamin A rises during light adaptation, most of it diffuses out into contiguous tissues and the circulation. Conversely, during dark adaptation the retina recaptures vitamin A₁ by binding it in non-diffusible form in rhodopsin (Wald, 1935-36b).

These migrations make an important contribution to visual physiology, since they connect the otherwise closed rhodopsin cycle with the general level and metabolism of vitamin A₁ throughout the body. They appear to find direct histological expression in the conditions which govern the appearance of Kolmer's droplets—lipoidal structures found under certain circumstances clustered about the outer limbs of the rods (Johnson and Detwiler, 1942). The droplets are prominent in histological preparations from dark-adapted animals, but are sparse in those from light-adapted eyes. They occur in large numbers in situations in which the retinene and vitamin A content of the retina is high: (a) dark-adapted tissues in which the destruction of rhodopsin by the histological fixative has liberated retinene₁; or (b) retinas light-adapted at 0° C, in which the thermal reactions which lead to the production and emigration of vitamin A₁ have been inhibited by cold. Conversely, Kolmer's droplets are scarce in situations which have permitted the diffusion of vitamin A₁ from the retina or prevented its return: (a) light-adaptation at room temperature; or (b) dark-adaptation in the cold, which by inhibiting the synthesis of rhodopsin has prevented the recapture by the retina of vitamin A₁. It seems from these experiments that the coagulation of retinal protein by the histological fixative sweeps retinene₁ and vitamin A₁ out of the structure of the outer limb to form the Kolmer droplets on its surface.

It was noted above that an isolated retina, though it can reverse the bleaching of rhodopsin to retinene₁ and protein, is unable to synthesize rhodopsin from vitamin A₁. Kühne (1878a, p. 8) made the remarkable observation that the retina regains this capacity when laid back smoothly upon a pigment epithelium. The reaction requires a living pigment epithelium, though not necessarily a living retina (Ewald and Kühne, 1878, p. 261). One might suppose this need for contact with the pigment epithelium to reside in the retina's dependence upon it for the transfer of material from the choroidal circulation. But the circulation is not required in this synthesis, since it proceeds in a frog eye completely removed from the body, though otherwise intact. Furthermore, in the human condition of retinal detachment, portions of retina which have risen from the underlying pigment epithelium are blind, though they possess an intact circulation. Sight may be restored to them by an operation introduced by Gonin in which the elevated sections of retina are laid back upon and attached at points to the pigmented tissue (cf. Duke-Elder, 1940). What it is that the pigment epithelium contributes to the synthesis of rhodopsin is not known; but it must be clear from the foregoing discussion that contact and diffusion phenomena play an important part in this process.

The synthesis of retinal photopigments in darkness is the basis of the sensory phenomenon of dark-adaptation, *i.e.*, the rise of visual sensitivity to a constant maximal level. The existence of this level shows that there are fixed limits to the quantities of photopigment synthesized in rods or cones. Judging from the constancy of threshold of the completely dark-adapted eye, these limits are maintained with considerable precision. What determines the maximum concentrations of photopigment in the retina? Not normally exhaustion in the supply of vitamins A, since small quantities of vitamin are always found in the dark-adapted tissue, and further supplies are continuously available from the circulation. The synthesis of photopigments must be limited ultimately by the supply of their specific proteins. It is for this reason that—contrary to a widespread belief—the sensitivity of the normal eye cannot be improved by dosage with vitamin A.

This consideration raises a neglected possibility in the etiology of night-blindness. There has been much interest recently in the transitory night-blindness associated with vitamin A deficiency, in which the synthesis of rhodopsin—and perhaps also of cone photopigment—fails, due apparently to simple reduction in the retinal availability of vitamin A₁. Congenital forms of night-blindness exist also, however, which are not accompanied by obvious anatomical lesions, and are not responsive to vitamin A therapy. Possibly such conditions involve the lack of specific photopigment proteins. A puzzling type of night-blindness recently observed in experimental human vitamin A deficiency, and highly refractory to administration of vitamin A, may also be of this nature (*cf.* Hecht and Mandelbaum, 1940; Steven and Wald, 1941).

It is not sufficiently appreciated that photopigment must form a considerable portion of the total structure of the rod outer limb. A frog retina of 3 mg dry weight may contain 1.25 microgms. of vitamin A₁ (Wald, 1934-35). On the conservative assumption that in the synthesis of rhodopsin one mol (286 g) of vitamin A₁ combines with about 18,000 grams of protein—a minimal molar unit of protein structure—this retina, when dark-adapted, contains about 0.08 mg of rhodopsin. Rod outer limbs probably account for less than $\frac{1}{2}$ the weight of the retina, or about 0.60 mg. On this basis, therefore, rhodopsin constitutes about 13 per cent of the outer limb. This is almost certainly a minimal estimate. It raises the possibility that the protein of the rod outer limb is largely, or even predominantly, rhodopsin-protein, and is an assurance in any case that this substance plays a considerable structural as well as chemical role in the retina.*

How is the bleaching of photopigments in the rods and cones transmuted into a neural excitation? It is difficult to suppose that liberated carotenoid groups act as chemical irritants comparable, for example, with the neurohumor acetylcholine, for few substances are so bland as the known carotenoids. In a curious series of experiments Kühne (1878c, p. 468) attempted to test directly the possible excitatory effects of unbleached and bleached rhodopsin solutions upon frog nerve-muscle preparations, with negative results. He also crushed retinas before and after bleaching, with the photoreceptor layer pressed against the tongue, and found no taste stimulation. The realization that the photopigments form a substantial portion of the oriented structure of the outer limb places this matter in a new light. In this case the bleaching of photopigment represents directly an appreciable disruption of the organization of the outer limb such as may constitute its excitation in every real sense.

* It follows that deficiency of rhodopsin-protein, suggested in the preceding paragraph to be one basis of night-blindness, amounts in effect to the structural disintegration of the rod outer limb. We may already have a histological description of this process. Johnson (cited in Detwiler, 1943) reports that in moderately vitamin A-deficient rats, rod outer segments degenerate and may entirely disappear. After several months of adequate feeding they regenerate to an approximately normal condition. These results offer a close parallel to the observation that in certain cases of experimental human vitamin A-deficiency, night-blindness is repaired only after 6 weeks to several months of a complete diet.

The alternation of oriented protein and lipid layers in the outer limb resembles closely that found in the axon sheath of nerve; it is found also in the stroma of the red blood cell, and may be very generally characteristic of protoplasmic surfaces (cf. Schmidt, 1938; Schmitt, 1936). It was remarked above that the photopigments may be oriented in the protein layers of the outer limb so that their carotenoid groups project into the lipoidal interstices. In this event the multiple interfaces between protein and lipid are actually composed largely of photopigment. If, as seems likely, surface structure plays as large a part in the excitation and recovery of rods and cones as it does in nerve, this consideration provides a ready explanation of the role of the photopigments in the visual process.

The Photopigments in Solution

Kühne attempted without success to extract rhodopsin from the retina with a wide array of organic and aqueous solvents. Finally, recognizing that the rod outer limb is very similar in composition to the red cell stroma and the myelin sheath of nerve, upon both of which bile salts exercise a strong lytic action, he tried this reagent upon the retina (1878b, p. 42). On exposure to bile salts solution the outer limbs shot "like rockets" from the retinal surface, lengthened and coiled "like worms," then spilled forth the lamellae of which they are composed "like coins shot out of a pipe." In the course of this disintegration rhodopsin went into solution. Until recently 5 per cent aqueous bile salts (sodium glycocholate, taurocholate, desoxycholate, or a mixture of these salts) remained its only known extractant and solvent.

Within recent years a number of new solvents have been found for the visual photopigments. Tansley (1931) introduced the use of the glucosides saponin and digitonin. The latter in 2 per cent aqueous solution is probably the most satisfactory solvent available for rhodopsin, and has proved equally effective for the extraction and solution of porphyropsin and iodopsin. Hosoya (1933) reported the extraction of rhodopsin with aqueous solutions of the plant glucosides panaxtoxin and kalotoxin, with 0.1-0.2 per cent sodium oleate, and with 2-3 per cent sodium salicylate. Several years later (1936) he added two snake venoms to this list; their efficacy is probably related to Lythgoe's observation (1938) that lysolecithin, a modified phosphatide formed from lecithin by cobra venom, and a powerful hemolytic agent, liberates rhodopsin from the rod in a concentration of $\frac{1}{10,000}$. Lythgoe (1938) also reported that rhodopsin is "liberated" by sodium palmityl sulfonate; but Smith (Smith and Pickels, 1940-41) found this pigment to be destroyed instantaneously by the closely related sodium dodecyl sulfonate.

All these substances are detergents—compounds characterized by the possession of polar and large hydrocarbon groups. Their solvent action upon the retinal photopigments is an example of their general capacity to carry hydrophobic molecules into aqueous solution, a property called hydrotropy by Neuberg (1916). The action of bile salts in this regard has been studied in detail and may serve as a model for the group (Wieland and Sorge, 1916; Rheinbolt, 1927; Verzár and Kúthy, 1929). The bile acids form water-soluble addition complexes of large size with a great variety of organic molecules. The binding involves their hydrocarbon rather than their polar groups; in general the larger the non-polar portion of a molecule, the more molecules of bile acid combine with it.

The complexes so formed are stable in composition, often beautifully crystallizable, and may be of very large size. So for example stearic acid, $C_{17}H_{35}COOH$, combines with 8 molecules of desoxycholic acid to form a water-soluble, crystalline complex of molecular weight 3420. Detergent molecules also combine with themselves to form large colloidal complexes. Digitonin on standing in solution aggregates to the point of precipitation; such solutions must be freshened before use by bringing to a boil. In this case also stable complexes of definite composition may be formed. Smith and Pickels (1940) have shown that in the ultracentrifuge digitonin

sediments with a sharp boundary, indicating particles of uniform size, of apparent molecular weight at least 75,000, and containing at least 60 molecules of digitonin per micelle.

This situation has confused initial attempts to measure the molecular weight of frog rhodopsin in digitonin and bile salts solutions. Diffusion measurements have indicated that this is some sub-multiple of about 810,000 grams (Hecht, Chase and Shlaer, 1937); ultracentrifuge studies have yielded apparent weights of about 270,000 (Hecht and Pickels, 1938) and about 100,000 (Lythgoe, 1938). Rhodopsin in such solutions, however, is not an individual but rather the nucleus of a complex with detergent molecules, to which rhodopsin itself may contribute only a small fraction of the mass. The measurements cited concern entire rhodopsin-detergent micelles, and offer no indication of the dimensions of the rhodopsin molecule alone. Our information of the latter has advanced little beyond the observation of Ewald and Kühne (1878, p. 454) that rhodopsin in bile salts solution does not diffuse through a parchment membrane.

Kühne (1895) made the technically important discovery that rhodopsin remains soluble and otherwise apparently unharmed following treatment of the retina with 4 per cent alum solution. Alum coagulates hemoglobin and other retinal proteins which otherwise enter the extracts, and in this way rhodopsin is singled out for extraction in a relatively pure condition. The value of this procedure can hardly be exaggerated, since rhodopsin is never available in more than minimal quantities and is scarcely approachable with the ordinary, wasteful methods of protein fractionation. Rhodopsin also survives the action on the retina of 4 per cent formaldehyde, which may be employed in its preparation in the same manner as alum. Either reagent can also be used in preparing porphyropsin; but alum treatment either destroys iodopsin or renders it insoluble (Wald, 1937b).*

The color and photosensitivity of rhodopsin are not destroyed by the death and subsequent coagulation and autolysis of the retina, nor in the course of intense rotting of the incubated tissue. Under these circumstances however rhodopsin may lose its solubility. This can be preserved by pickling the retina in 10 per cent brine (Ayres, 1878). Brine also has been reported to restore the solubility of rhodopsin when, as occasionally happens, it is lowered by alum treatment (Kühne, 1895).

These observations furnished the basis for Kühne's final directions for preparing rhodopsin solutions (1895). They have since been found equally effective with porphyropsin, and except for the alum treatment, with iodopsin. After removal of the anterior portions of the eye and the vitreous humor, the entire fundus is hardened in 4 per cent alum. The retina is dissected out, laid in water for one hour, then in 10 per cent brine for several hours. Rhodopsin is extracted with at least 4 per cent bile salts. To prevent putrefaction the final solution may be saturated with sodium chloride. For subsequent purification of such solutions, advantage may be taken of the fact that rhodopsin is precipitated from bile salts solution by saturation with magnesium sulfate or half-saturation with ammonium sulfate; the bile salts come down with the photopigment. Minor variations of all these procedures are still in use. The most notable innovations since Kühne have been the replacement of bile salts by digitonin, the use of the centrifuge to replace tedious and wasteful filtrations, and most important of all, the use of buffers to regulate the pH of the final solutions.

For the rest, the properties of the retinal photopigments are those common to proteins. Many of them, including several already mentioned, were described in the

* Glycerol also does not injure rhodopsin, and Ewald and Kühne (1878, p. 454) describe a mixture of 1 part rhodopsin in bile salts solution with 3 parts glycerol of which they remark the striking depth of color and high photosensitivity. Saito (1933) also has studied the behavior of rhodopsin in mixtures of 10-100 per cent glycerol with water. The capacity of this pigment to withstand admixture with glycerol has recently been rediscovered and used to good advantage in a study of its properties at -73°C (Broda and Goodeve, 1941-42).

case of rhodopsin by Ewald and Kühne, though the conclusion that this pigment is a protein was drawn only recently (Wald, 1935-36a). The primary data which identify these substances as proteins involve their destruction in ways characteristic of protein denaturation.

Rhodopsin and porphyropsin are rapidly destroyed by exposure to a variety of typical protein denaturants: alcohols, acetone, chloroform, heavy metal ions, and mineral acids and alkalies. Rhodopsin is destroyed by warming above 52° C (Ewald and Kühne, 1878, p. 440), porphyropsin above 62° C (Wald, 1938-39b). This process is accelerated in acid or alkaline solution; and in desiccated retinas rhodopsin survives heating even to 100° C (Ewald and Kühne). I have calculated from the latter authors' crude measurements of the velocity of heat destruction of rhodopsin at various temperatures an apparent activation energy of about 75,000 cal per mol in the retina and about 40,000 cal per mol in aqueous solution. Lythgoe and Quilliam (1938) have recently obtained very nearly the latter value in a excellent reinvestigation of the heat destruction of rhodopsin in solution. All these observations are typical of the heat denaturation of proteins.

The differences which Ewald and Kühne observed in the responses of rhodopsin to heat in the retina and in solution suggest some profound alteration in its structure as a result of extraction. This possibility should be re-examined with modern procedures. Ewald and Kühne (1878, p. 392) also found rhodopsin obtained from rabbit retinas to be much more sensitive to heat than that of frogs, and concluded that the rhodopsins of various animals, like their hemoglobins, may in general differ chemically. The parallel may now be recognized as exact, since such specific differences, as in the case of hemoglobin, do not involve the prosthetic group but are confined to the protein portion of the rhodopsin molecule.

Like other proteins, rhodopsin is amphoteric. Solutions prepared from frog retinas have an isoelectric point, determined by the moving-boundary method, at about pH 4.5 (Wald and Raymont, cited in Wald, 1938-39b). This observation has been confirmed by the microelectrophoretic measurements of Broda and Victor (1940) on frog rhodopsin adsorbed on quartz particles, which show an isoelectric point at pH 4.47. Broda and Victor found the isoelectric point of such preparations to rise to 4.57 on irradiation, indicating that the bleaching of rhodopsin makes the molecule slightly more alkaline. They recall that the isoelectric point of globin is 0.7 pH unit higher than that of hemoglobin, and suggest that their comparable observation on rhodopsin is consistent with the view that in bleaching this molecule is cleaved as described above.

Chemical Pacemakers and Physiological Rhythms

HUDSON HOAGLAND

The Physiological Laboratories, Clark University, Worcester, Mass.

INTRODUCTION: BIOELECTRIC POTENTIALS AND METABOLISM

Living cells are continuous converters of energy, taking in foodstuffs and usually oxygen and excreting carbon dioxide and other metabolites. Within each cell are many specific oxidative and hydrolytic enzymes which promote in stepwise sequences the degradation of foodstuffs coming to the cell from its immediate environment of lymph or other aqueous media. Membranes separating the cell's contents from its environment are selectively permeable as a result of their peculiar colloidal properties. Because of the steady-state flow of substances across the cell walls, the latter becomes the source of interesting electrical properties. The interiors of most living cells are at electrical potentials different from their exteriors. While a few plant cells have been found in which the resting inside potential is electrically positive to the outside, nearly all living cells that have been examined are electrically negative inside with respect to their external membranes. As a consequence, injured regions of most cells, since they represent internal portions, are likewise electrically negative to uninjured (external) regions. The potentials so measured are spoken of as demarcation or injury potentials. In muscle and in nerve cells, for example, they are of the order of 60 millivolts.

Studies of large water-inhabiting plant cells by Osterhout^{42, 43} and his colleagues indicate that the resting potentials of these cells are primarily due to diffusion potentials of potassium. The ionic constitution of the cell sap, as determined by direct chemical analysis after its extraction, is found to be strikingly different from the normal surrounding medium bathing the cells. Differences of concentration of diffusible substances across membranes impermeable to certain osmotically active constituents might result from a true thermodynamic equilibrium, but this is not the case for living cells (for a discussion of the Donnan equilibrium and its applications, see Bolam⁴).

The Donnan principle requires for ionic activities the relation

$$a_{K_i} \div a_{K_o} = a_{Na_i} \div a_{Na_o} = a_{H_i} \div a_{H_o} = a_{Cl_o} \div a_{Cl_i}$$

where a is activity and the subscripts i and o refer to the inside and the outside of the membrane. Analysis, however, makes it clear that these conditions are not even approximated for living plant cells. Since the solutions inside and outside have roughly equal total ionic strengths, it is permissible to use ionic concentrations instead of activities for comparative purposes. In the case of the marine plant cell, *Valonia*,

for example, the pH of the sap is 5.8 and that of the sea water in which it lives is 8.0, and we have⁴¹

$$\frac{K_i}{K_o} = 41.60; \frac{Na_i}{Na_o} = 0.18; \frac{H_i}{H_o} = 158.49; \frac{Cl_o}{Cl_i} = 0.97.$$

The inequalities of these values are conspicuous, and prove that the cells are not in true equilibrium with their environments. This type of disequilibrium has been demonstrated in recent years for many plant and animal cells, and is in fact the general rule.

One way to account for the concentration differences of Na and K inside and outside of the cell is to assume that K and Na enter because the thermodynamic potential of KOH and NaOH is greater outside than it is inside, that is

$$(K_o)(OH_o) > (K_i)(OH_i)$$

The protoplasm is found continuously to produce acids (HA) as metabolic products which tend to accumulate in the sap and thus lower the right-hand product of this expression by the neutralization of OH_i . KOH and NaOH then enter, transforming HA to its salts. These salts must then diffuse out of the sap. All this requires energy, which is produced by the chain of metabolic reactions in protoplasm, forming as a primary end product the acid CO_2 (i.e., H_2CO_3). Other acids incidentally produced by certain plants, such as malic, oxalic, citric, and tartaric, also may serve the same purpose; only when the cellular metabolism is inhibited do the ratios of diffusible electrolytes approach a Donnan equilibrium. Only dead cells are in true equilibrium with their environments.

While this hypothesis has been supported by a variety of evidence from Osterhout's laboratory, D. R. Hoagland and his collaborators have obtained experimental evidence opposed to the view that K concentration in cells depends on the $(K)(OH)$ gradient. These workers have shown that electrolyte concentration in a variety of forms of plant cells is directly dependent upon the carbohydrate metabolism of the cell, but the mere production of CO_2 in the sap does not appear to bring about the concentration. For a review of this subject see Hoagland.^{23a} For the purposes of our subsequent discussion of pacemakers, the intimate mechanism underlying electrolyte gradients across cell membranes is not important. The significant thing is the existence of well established quantitative relations between metabolism, electrolyte gradients, and bioelectric potentials. Blinks,^{3a} in a recent review of this matter, has written:

"In conclusion we may state that metabolic processes appear to be connected with permeability and electrical phenomena, not only in the formation of organic ion gradients, and of membranes responsible for the manifestation of potentials, resistances and capacities, but for their maintenance, and their alteration under various influences. The nature of these alterations, reflecting the nature of the cell surface itself, is not yet evident, although acidity changes are suggested in some cases."

The mobility of potassium is much greater than that of other substances normally traversing the cell membranes. It thus produces correspondingly large diffusion potentials. Its mobility in protoplasm is about 85 times as great as is that of chloride and 40 times as great as sodium. NH_4 , Li, Mg, and Ca have mobilities lower than Na. The order of mobilities is very different from that in water, thus indicating that the protoplasmic surfaces are non-aqueous.^{42, 43}

A mechanism similar to those involved in plant cells may also account for resting potentials in other tissues, although caution must be exercised in these considerations. Cowan⁶ has shown the importance of potassium in determining potentials in nerve fibers. For a discussion of the role of potassium in muscle the reader is referred to a recent review by Fenn.¹¹

Cells may be locally depolarized by chemical, electrical and mechanical stimuli, and such local depolarization may initiate a propagated wave of electrochemical change called an action current. The action current sweeps over the cell and may, at one-way synaptic junctions between neurones, be propagated from one cell to another. The propagated region of activity in nerve and muscle is, in general, electrically negative to the inactive region. For a brief interval following a propagated disturbance the tissue is completely refractory to further stimulation. Metabolic recovery of excitability takes place in nerve and muscle cells in a few thousandths of a second, and during this interval the excitability returns to its normal resting level, as can be determined by testing with stimulating electrical shocks of varying strengths applied at intervals after an initial effective stimulus.

It is not the purpose of this paper to discuss the subject of action currents, and the reader is referred to standard physiological texts for further information on this subject. The points we wish to make thus far indicate that cellular metabolism maintains cell structure and function by a dynamic steady state. The cell membranes, constituting an essential part of this structure, are electrically polarized as a consequence of the energy of cell metabolism. The membrane's permeability is modifiable by stimuli. An action current, once started, sweeps over the cell's protoplasm by a mechanism whereby the electrically active region, as defined above, serves as an electrical stimulus (cathode) to adjacent inactive regions thus causing them in turn to become electrically active. Such propagated action currents arriving at muscles may, through special intermediate mechanisms, stimulate them to contract. Similar propagated disturbances arriving at the central nervous system over afferent nerve fibers inform us about our environment.

Nerve impulses have been defined as a conducted tendency to excite, and action potentials are their readily determinable signs. As a corollary to the fact that the nerve fiber is briefly refractory after the passage of an impulse, the action potentials can travel over a fiber only in quanta. Even the most intensive stimulus to sense organs can, as Adrian¹ was the first to show, only increase the frequency of the number of impulses in a *single* nerve fiber. Owing to statistical variations in the thresholds of sense cells,²⁴ more sense organs and hence more sensory fibers in a nerve trunk are brought into play as the intensity of stimulation increases. Thus with increasing strength of stimulus the frequency of afferent nerve impulses alone increases. The magnitude of the action potential along a given fiber is independent of the initiating stimulus, since it depends only on the local polarized conditions of the fibers, which in turn are determined by their local metabolic steady-states. The electrical activity along the tissue is thus produced by the local release of stored potential energy. Amplitude increases in action potentials recorded from a nerve trunk, with increasing strength of stimulation to sense organs, results from the increased number of active fibers under the lead electrodes, and the shunting effect of inactive tissue.

We thus see that rhythmicity of nerve impulse discharge is characteristically set up by stimulating sensory cells connected to the nerve fibers. In the presence of a constant physical stimulus the sensory cells may show a progressive failure to initiate nerve impulses, so that the frequency declines in time. The rate of this "adaptation" or "accommodation" to a constant stimulus varies considerably from one type of sense organ to another. Some sense organs, such as touch spots on the skin, adapt so rapidly to a constant stimulus as only to set up one or two impulses per nerve fiber, while other kinds of sense cells, such as muscle and joint sense organs, discharge impulses repetitively for many minutes with little decline in frequency.¹ The mechanism of accommodation of excitable tissue has received much attention from physiologists.^{19, 20, 28} In some tissues a region of injury or a constant electrical current produces no impulses after the initial burst when the injury was made or the

circuit closed. Other tissues may discharge impulses repetitively from similar regions, which thus act as pacemakers for the activity.

A morphological pacemaker is usually regarded as a region of an organ or tissue from which rhythmic activity arises. Thus the sinoauricular node of the vertebrate heart is spoken of as its pacemaker. Pacemaker conditions may be established experimentally in excitable tissues. The application of a drop of chloroform to the filamentous plant cell *Nitella* may, by locally reducing the resting potential, set up local circuits between the normal and treated tissue which start waves of action currents along the cell. These waves may be rhythmically repeated as soon as the tissue recovers from the refractory state set up by the previous impulse.⁴⁰ In like manner a drop of 0.05M KCl, by locally reversing the resting potential of *Nitella*, acts to produce a pacemaker locus. The ends of certain cut or damaged mammalian nerve fibers have been shown to initiate rhythmic discharges of nerve impulses.² Similar injury discharges have been described in certain sensory nerves of fishes.²⁶ Presumably local depolarization of the nerve membranes resulting from the injury acts as a region of constant stimulation, causing the repetitive discharge. In all these cases a steep and sharply localized concentration gradient of electrolytes between the damaged or treated region and the normal tissue is necessary to produce rhythmicity. Lillie's well-known iron wire nerve model^{34, 35} has been made to discharge rhythmically by immersing the wire in nitric acid, 60-80 volumes per cent, and inserting one end of it in a snugly fitting glass tube, thus limiting diffusion of acid around the sheathed end. If a wave of activity is then initiated in the wire it is usually found that the sheathed tip acts subsequently as a pacemaker, setting up a repetitive discharge at a frequency limited by the recovery period of the unsheathed wire. After the first impulse the sheathed part of the wire does not become passivated with the usual bright oxide layer, and effervescence goes on continually in the sheathing tube. This is brought about by the limited diffusion of acid in the sheathed part, which, after the passage of one wave of activity, becomes locally so reduced in concentration (ca. 53 per cent) as to be unable to repassivate the sheathed tip. The continuously oxidizing region, anodal to the passivated wire by about 0.7 volt, thus initiates repetitive discharges.

The problem of pacemaker mechanisms is one of very wide interest. Sensory cells, when stimulated, set up excitatory states which function with respect to the nerve fibers as pacemakers for the repeated discharge of impulses. Thus the essentially *arhythmic* photochemical changes initiated in the retina by light develop rhythmic discharges of impulses over the optic nerve. Mechanoreceptors, such as Pacinian corpuscles in joints and tendons and muscle spindle receptors informing us of muscle tension, fire impulses repetitively at a declining frequency depending on the strength of stimulus and on the rate of accommodation of the ending.

In recent years it has become well established, following the work of the late Hans Berger and others, that most brain centers are normally engaged in rhythmic fluctuations of electrical activity. These fluctuating potentials in man can be picked up through skull and scalp by electrodes attached to the scalp. That they come from the cerebral cortex has been established beyond question. The most characteristic pattern obtained through the human skull from resting subjects with closed eyes is a regular sinusoidal rhythm at a frequency of about ten per second which is known as the alpha rhythm, and which is usually most clear over the back of the head external to the occipital cortex, known to be primarily concerned with vision. Opening the eyes breaks up this uniform rhythm because the brain cells producing it are electrically synchronized and pattern vision, projected from the retina to the occipital cortex, breaks up the synchronized "resting" activity of these cells.

Actually there has been detected a whole spectrum of electrical waves from the brain ranging in frequency from less than one per second to around fifty per second.

Certain frequency bands, however, are more conspicuous than others and their prominence may vary considerably from one normal individual to another. Variations in brain wave patterns have also been extensively studied in connection with a variety of neurological disorders. For a review of brain-wave work, especially from the clinical side, the reader is referred to the "Atlas of Electroencephalography" by Gibbs and Gibbs.¹⁵

We thus see that the central nervous interaction of groups of neurones involves complex pacemaker considerations. Certain neurones of the respiratory center fluctuate rhythmically and independently of afferent impulses from peripheral sense organs. This was clearly indicated by the experiments of Adrian and Buytendjik,³ who demonstrated that the brain stem of the goldfish, when completely removed from the body, continues to manifest electrical potential fluctuations at a frequency characteristic of the normal gill movements. Subsequently work of Gesell (see especially reference 14) and his collaborators has demonstrated intrinsic rhythmicity of the mammalian respiratory centers. These rhythms, like heart rhythms, are modifiable by afferent nerve impulses, but they are basically a product of the center's metabolism—just as the myogenic heart rhythm is a result of the heart's own metabolism.

Chemical Pacemakers

One might well ask at this point, how can continuous steady-state chemical events produce electrical rhythmicity in tissues? A model originally proposed by Van der Pol⁵² in connection with cardiac rhythmicity may be helpful in thinking about this matter, although the subsequent discussion in no way depends upon the applicability of this, or any other specific model, to living tissues.

Fig. 1, from a paper by Fessard,¹² shows the essential principles of this model,

FIGURE 1. Figure from Fessard¹² showing at left a neon tube, N , in circuit with a condenser, C , battery, V , and resistance, R . The tube fires intermittently, as shown on the right; x is voltage across the condenser and i is current across the tube.

which consists of a neon tube connected in parallel with a condenser and in series with a battery and a resistance. Such a tube will flash rhythmically at frequencies determined by two factors. One of these is the impedance of the circuit as measured by the condenser capacity and the resistance. The other is the speed of the physico-chemical events going on in the battery. If the impedance is constant the frequency will vary with what we might refer to as the speed of the oxidative "metabolism" of the battery. In this model time is required for the battery to load the condenser to its firing threshold across the tube. Other things being equal, the faster the battery's oxidations, the more rapidly the charge can be loaded and hence the greater the frequency of flashing.

This analogy to living tissues is suggestive, since living cell walls have a definite measurable impedance and are stimulated by critical voltages. Moreover, within the cell respiration may be considered analogous to the battery part of the model in determining recovery of the cell's excitability. As a byproduct of respiration, electrical polarization takes place across the membranes which, in some cells, may act as a stimulus when critical voltages are reached. The fact that a mouse's heart beats normally six times as fast as a man's heart does not, of course, imply that the mouse's

heart is metabolizing six times as fast. The absolute differences would presumably be due to differences in the electrical constants of the tissues. We might, however, expect that increasing or decreasing the respiration of heart muscle in the two cases might proportionally increase or decrease the frequency.

In the battery part of the model, oxidation is proceeding in a series of physico-chemical steps. Whichever one of these is slow with respect to the others may be conceived as acting as a sort of bottleneck or pacemaker. Changes in the flash frequency might thus be due to changes in the speed of one limiting step in a series. In cell respiration we know that foodstuffs are broken down in sequential steps yielding energy. If one of these steps is slower than the others it, too, may serve as chemical pacemaker. The chemical pacemaker is thus analogous to the idea of the industrial bottleneck which, unfortunately, we have heard so much about of late. Foodstuff molecules, on being dismantled of their hydrogen, yield energy which determines velocities of physiological events. The foodstuff molecule is degraded in the cell in a stepwise series of reaction, each step under the control of a specific enzyme system. A slow enzyme step in such a chain is analogous to a slow worker on a continuous assembly line engaged in assembling or disassembling a complex machine. His speed determines the final output. In like manner one enzyme-catalyzed step in a sequence may directly determine the speed of some complicated physiological process. We shall presently discuss a method of studying chemical bottlenecks of this type in some detail.

To summarize: A *morphological pacemaker* is a region of tissue which, after discharging, recovers its excitability more rapidly than other regions of the same cell system. Its short recovery period thus makes possible discharge from this region somewhat before adjacent regions have fully recovered their excitability. Thus in a spontaneously rhythmic system like the heart, such a region becomes the origin of the beat.

A *chemical pacemaker*, on the other hand, is the slowest physico-chemical event of a sequence determining the energy exchange, and hence the frequency of rhythms of the morphological pacemaker. It might thus, for example, be the slowest step in oxidative recovery of excitability taking place in the most rapidly recovering cells of the sinoauricular node of the vertebrate heart. Thus we see that a single, simple continuous reaction of a complex series, if it is relatively slow, may theoretically set the pace of a physiological rhythm.

TEMPERATURE AND ENZYME PACEMAKERS OF PHYSIOLOGICAL RHYTHMS

It should be possible to test the view that physiological rhythms are dependent on the velocities of simple chemical pacemakers, by studying these rhythms and also biological oxidations as a function of temperatures.

The Arrhenius equation may be written as follows:

$$v = ze^{-\mu/RT} \quad (1)$$

where v is chemical velocity, z is a constant, e is the base of natural logarithms, T is the absolute temperature, R is the gas constant, and μ is the critical thermal increment or energy of activation, *i.e.*, the amount of energy per mol over and above the average energy of the system that molecules must acquire before they can react. In the literature of physical chemistry, E is used instead of μ for the energy of activation. To avoid the implication that the μ values of biological processes are necessarily identical with activation energies as used by physical chemists, Crozier¹⁰ originally introduced the symbol μ and referred to it as the "temperature characteristic" rather than as the energy of activation. Recent work, to be described below, suggests that E and μ are probably identical.

Taking logarithms on both sides of equation (1) we obtain

$$\log v = c - \mu/2.3RT \quad (2)$$

If experimental data conform to the Arrhenius equation, it is thus clear that a plot of $\log v$ vs $1/T$ should yield a straight line with ordinate intercept at c and negative slope of $\mu/2.3R$.

If frequency (f) of some physiological rhythm is directly proportional to the velocity of some underlying chemical pacemaker we may write

$$f = kv = kze^{-\mu/RT} = ae^{-\mu/RT} \quad (3)$$

and again taking logarithms

$$\log f = c' - \mu/2.3RT \quad (4)$$

Thus in comparing equations (2) and (4) it is clear that a plot of $\log f$ vs $1/T$ would give the same value of μ as if we plotted $\log v$ vs $1/T$ directly. In a log frequency plot the intercept on the ordinate axis would be at c' instead of at c . The two plots would give parallel lines of the same negative slope equal to $\mu/2.3R$, or $\mu/4.6$, since R is 1.99, or 2 calories per mol per degree.

It is thus clear that an interesting test of the master reaction principle might be had by comparing μ values for frequencies of physiological rhythms with those for directly measured biological oxidations both for cell systems as a whole and for isolated respiratory enzyme systems acting with their respective substrates.

The Arrhenius equation describes with precision a large number of homogeneous and heterogeneous reactions both in solution and in the gaseous state. The reader is referred in particular to Hinshelwood's monograph²³ for a discussion of the equation and the concept of the energy of activation. For our purposes we wish to see to what extent the equation may be used to describe physiological and biochemical processes with the view to examining μ values as possible indicators of specific chemical pacemakers.

The Arrhenius equation has been applied by a host of workers to many hundreds of biological rates and is found to describe the data in most cases. The mere fact of a fit to data of this very general relation is not especially interesting. What is more significant is the order of magnitudes of the μ values and the fact that they occur, not distributed at random, but grouped in certain well-defined modes.

Fig. 2 shows an Arrhenius equation plot of data from Navez³⁹ for the rate of

FIGURE 2. CO₂ production of seedlings of *Vicia faba* as a function of temperature, from Navez.³⁹

production of CO₂ by seedlings of the plant *Vicia faba*. Above 21° C the relation in this particular case falls off. Note that because of the reciprocal method of plotting low temperatures are at the right, high temperatures at the left on the abscissa.

Fig. 3, on the other hand, shows a group of μ plots from a paper of Fries¹³ on

FIGURE 3. Frequencies of beating of cockroach hearts as a function of temperature. From Fries.¹³

the frequency of heartbeats of cockroaches as a function of their internal body temperatures. The μ averages 12,500 calories.

Fig. 4, from Crozier,⁷ shows data obtained by three different workers at different

FIGURE 4. Data from three independent observers for the frequency of chirping of crickets as a function of temperature, from Crozier.⁷

times and places relating the frequency of chirping of crickets to temperature. The μ is 12,200 calories, a value frequently encountered in connection with rhythmic activity in insects.

Crozier¹⁰ in 1925 made a frequency distribution plot of some 360 μ values for diverse biological rates. Fig. 5 from his paper shows clearly that the μ values are

FIGURE 5. Frequency distribution plot of 360 μ values for diverse biological rates, from Crozier.¹⁰

not distributed at random but are grouped in certain modal values. Over 90 per cent of the μ values are those for physiological rhythms such as breathing movements, heartbeat frequencies, movements of appendages, cilia, etc. of "cold-blooded," *i.e.*, poikilothermous animals.

In 1936²⁹ the writer published a figure for the distribution of μ values occurring in the literature for some 76 studies of biological oxidations. Fig. 6 is a reproduc-

FIGURE 6. Frequency distribution plot of 74 μ values for diverse cellular respiration experiments, from Hoagland.²⁹

tion of this figure. It is clear that these μ values group in essentially the same major modal categories as do those of the data for rhythmic processes earlier figured by Crozier. Chi square tests have demonstrated the statistical reality of these modes.²⁷ The most conspicuous μ groupings are at 16-17,000 calories, 11,000 calories and 8,000 calories.

To account for the often recurring μ values in different protoplasmic systems, Crozier originally suggested that the modal values may correspond to energies of activation of specific catalyzed links in sequential steps in the chemical chains constituting cellular metabolism. The wide recurrence of certain respiratory enzymes in highly diverse tissue systems is in conformity with this view. Catalysts promote reactions by so orienting molecules that particular bonds can be broken in a way

not usually possible except by a marked increase in kinetic energy produced at elevated temperatures. In a chain of catalyzed reactions we should expect the slowest link to act as chemical pacemaker. If in different cell systems the slowest link is now one and now another of a few enzyme systems common to many different tissues, a multimodal distribution of μ values such as has been obtained might be expected. Moreover, experimental conditions altering the ratio of velocity constants of the steps in the sequence might be found to shift the μ from one of the prominent characteristic group values to another. Such experimental shifts of μ from one of the 3, 11, or 16 thousand groups to another have been described.²⁷

The oxidation of ferrous to ferric iron *in vitro* requires an energy of activation of 16,200 calories (for citations see Crozier⁸). In many cell respiratory processes it has been demonstrated by direct chemical methods that an enzyme system (cytochrome-cytochrome oxidase) involving iron is often the limiting factor,⁵³ and it is known that the catalytic iron of this system undergoes oxidation and reduction. This fact is at least consistent with the predominance of 16,000 calories among physiological μ values.

Most physiological rates are described by the Arrhenius equation, but some are not. For systems involving two or more concurrent chains of processes with different μ values, each process of which contributes appreciably to the measured rate, we should not expect a rectilinear relation. The plot should be concave upward.⁹ When such concurrent processes are analyzed *separately* they are found to give rectilinear relations.²²

Some Arrhenius plots show sharp breaks in the curves at critical temperatures. The significance of these breaks has been discussed elsewhere in a number of papers from Crozier's laboratory in the *Journal of General Physiology*. Their presence is consistent with the view that in a sequence of reactions, the same reaction may not be the slowest or master reaction over an extensive temperature range, since each step varies independently with temperature (*i.e.*, has its own μ value) of each other step. Thus one reaction may be slowest over part of an experimental

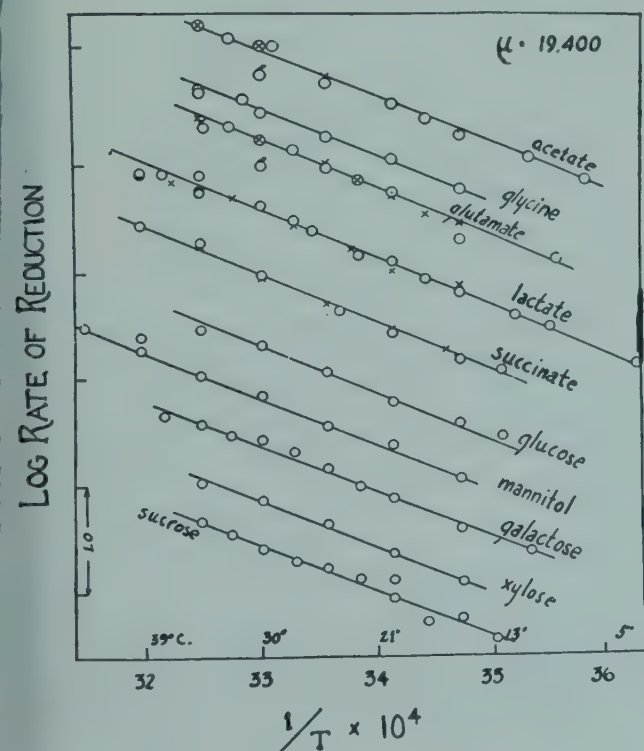

FIGURE 7. Log of rate of reduction (calculated from the time required for 75 per cent reduction of methylene blue) in presence of various substrates by a suspension of *Escherichia coli* plotted against $1/T$. μ in the Arrhenius equation = 19,400. O refers to the series of determinations made with a first bacterial preparation; X to determinations made with second separate bacterial preparations. For lactate X refers to determinations made with a preparation consisting of autolyzed cells. From Gould and Sizer.¹⁶

temperature range and another slowest over another part, *i.e.*, the temperature rate curves may intersect at a critical temperature. The μ plot under these circumstances would be expected to show a break in slope at the critical temperature. These findings are entirely consistent with the master reaction principle, and indeed strengthen it. Burton⁹ has criticized the master reaction principle in relation to μ values, but he has, in doing so, made certain assumptions not involved in the present discussion. For an answer to these criticisms see Hoagland.³⁰

Sizer⁴⁷ and Gould and Sizer¹⁶ have demonstrated that μ values of biological processes may be indicative of specific enzymes. Sizer⁴⁸ has shown that the hydrolysis of sucrose and of raffinose by yeast invertase gives a μ of about 12,000 calories which is independent of pH changes ranging between 3.2 and 7.9 units and is not altered by the presence of electrolytes. Gould and Sizer have shown that the decoloration of methylene blue by bacteria (*b. coli*) in the presence of ten widely different substrates yields a μ value of 19,400 calories for the dehydrogenations and is thus independent of the gross nature of the substrates. Fig. 7, taken from their paper, demonstrates this.

Earlier in this discussion, mention was made of electrical brain waves which may be recorded in man through skull and scalp. In 1936 the writer²⁰ studied the effect of internal body temperature on the alpha brain wave frequencies of a group of normal persons and a group of patients suffering from brain syphilis or general paresis. The body temperatures of the subjects were raised, in the cases of some of the patients, to over 106° F by passing high-frequency alternating currents through their well wrapped bodies.*

Fig. 8 shows alpha rhythms for a normal subject at each of a number of body

FIGURE 8. Sample of brain waves from a normal human subject showing strong alpha rhythms. Mean frequencies for each temperature for 80 seconds of recording (ca. 800 cycles) with probable errors shown at left. From Hoagland.²⁹

temperatures. Fig. 9 is an Arrhenius equation plot of these data yielding a μ of $8,000 \pm 200$ calories. Fig. 10 shows a composite plot of all the data. The lower band of points ($\mu = 8,000$) represents data on three normal subjects, a multiple sclerosis patient and two patients who were least advanced in their paretic symptoms. The middle band of points corresponds to data from two decidedly more advanced paretic patients ($\mu = 11,000 \pm 300$ calories). The upper band of points represents data from two very advanced paretics ($\mu = 16,000 \pm 300$ calories). Each point is a mean of 80 seconds of record (about 800 alpha cycles).

It should be pointed out that the ordinate intercepts of these plots are here meaningless; the data are arbitrarily arranged on the figure in order to compare the slopes or μ values. The brain-wave frequencies of the advanced paretic patients are

* Large currents at frequencies of the order of a million cycles may be safely passed through the body without shocking or stimulating its tissues. To stimulate, a current must pass for an interval of time that varies hyperbolically with its magnitude. To stimulate, currents must move electrically charged particles definite distances and must hence act for appreciable times in a given direction. Oscillating a million times a second, they cannot stimulate.

FIGURE 9. Arrhenius equation plot of alpha brain-wave frequencies from the same subject whose brain waves are shown in Fig. 8, from Hoagland.²⁹

FIGURE 10. Composite plot of data showing a μ of 8,000 calories for three normal persons, a multiple-sclerosis patient and two very early general paretics. $\mu = 11,000$ for two more advanced paretics and 16,000 for two very advanced paretics. From Hoagland.²⁹

not faster at normal body temperatures than are those of normals. They are, however, more rapidly *accelerated* with rising temperatures. The results indicate that these μ values are energies of activation of particular chemical pacemaker links in respiratory reaction chains in the cells producing the alpha rhythms. Evidently the advancing spirochete infection shifts the chemical pacemaker from one of these links to another.

In view of these findings a series of experiments was carried out by the writer and various collaborators to test further metabolic factors underlying central nervous rhythms; the following results were obtained:

Lowering blood sugar by insulin below a critical level and thus lowering brain sugar causes the alpha frequencies in man and dogs to fall. The frequencies recover when sugar is injected.^{31, 33} Brain O_2 consumption follows the curve of sugar after insulin administration, and the alpha frequency curve, within certain limits, parallels both these curves.²¹ Dinitrophenol and thyroxin, well known metabolic stimulants, cause the frequencies to increase.^{32, 45} Phentobarbital sodium, which inhibits brain respiration *in vitro*, slows the cortical frequencies.³³

These findings are, of course, *not* to be interpreted as meaning that the *only* modifiers of brain-wave frequencies are necessarily changes in cell respiration. Afferent stimulation which modifies frequencies may do so by locally changing cell respiration or by modifying the electrical constants of the cells or their connections by direct permeability changes. Absolute differences in frequencies of different cell groups also are not to be regarded as due to corresponding absolute differences in rates of O_2 consumptions, but rather to differences in structure (impedance) of the cell walls or connecting fibers. These considerations in no way militate against the view that *relative* frequency changes under specific conditions are due to changes in rates of cell metabolism.

The prominence of the μ values of 8, 11 and 16 thousand calories in particular leads to the question as to what specific steps in cellular respiration they may correspond to. Reasons have been mentioned above for thinking that the last of these values may be association with an iron-catalyzed pacemaker step. This view is justified by the following considerations. Iron pigment, which occurs in all normal brains in a characteristic manner, is found to stain in advanced parietic brains and is distributed quite differently. The parietic brain iron occurs in colloidal spicules scattered about as if it had been precipitated in some way by the infection. In fact this phenomenon is used as a valuable postmortem test to tell just where the spirochete has been busy in the brain.³⁸ This suggests that iron, normally plentifully present in the cytochrome-cytochrome oxidase system in brain, has become inactivated catalytically. For evidence for this see reference.¹⁷ A reduction of normal catalytic cytochrome brain iron might thus slow this particular link to a point where it would become the pacemaker step, thus shifting the respiratory measure to a μ of 16,000 calories which we have seen to be characteristic of the oxidation of ferrous to ferric iron.

It occurred to the writer that a check on all this might be had in the following way. If an oxidative process catalyzed by an enzyme system containing two or more components *acting in sequence* were to be studied *in vitro*, it should be possible to obtain different μ values for the process by partially poisoning different components of the system, thus making now one and now another step the slow one. Furthermore, if one of these components be an iron-containing enzyme, one of the two μ values might turn out to be $16,000 \pm$ calories in terms of the above considerations. The objection might be raised that the enzyme-catalyzed processes *in vivo* need not necessarily correspond to such processes *in vitro*. This is true but the objection has been met at least in part by Sizer,⁴⁸ who has shown that the invertase inversion of sucrose by living yeast cells and by yeast cells killed in toluene yields identical μ values.

Such a desired enzyme system may be extracted from the beef heart by methods described by Stotz and Hastings.⁴⁹ The system has been shown by these workers to oxidize succinate to fumarate and to involve at least two components, succino-dehydrogenase and cytochrome-cytochrome oxidase. The reaction is followed by measuring the oxygen consumption manometrically in Warburg vessels. The reaction for our purposes may conveniently be written as follows:

In this reaction succinic acid is oxidized to fumaric acid, and oxygen activated by the oxidase system is consumed. The oxygen combines with hydrogen from the succinate activated by its dehydrogenase. The system is of special interest since it is almost universally present in tissues and since nearly all respiration proceeds through it.⁵⁰ Both succino-dehydrogenase and cytochrome-cytochrome oxidase are amply present in brain.⁴⁴ Torrès⁵¹ has shown that 97.5 per cent of respiration of rat-brain cortex involves the cytochrome system which we know functions sequentially with succino-dehydrogenase.

Stotz and Hastings have shown (a) that the enzyme as prepared by them is free of fumarase, since the amount of fumarate formed agrees stoichiometrically with the oxygen consumed, indicating that none of the fumarate formed by the oxidation of succinate is hydrolyzed to malic acid. (b) The reaction follows first-order kinetics. The value of the velocity constant does not deviate from the mean significantly for the first 85 per cent of the reaction, thus indicating that there is no destruction of the enzyme, at least for the first 85 per cent of the reaction. (c) The addition of $6.0 \times 10^{-6} M$ NaCN, or $2.0 \times 10^{-5} M$ selenite per 0.5 ml enzyme solution stops the oxidation of succinate completely. (d) Oxidase activity can be studied independently, since cytochrome-cytochrome oxidase can oxidase *p*-phenylenediamine without a dehydrogenase and the dehydrogenase activity can be studied independently if a hydrogen acceptor, such as methylene blue, cresyl blue, or some other suitable dye requiring no activating catalyst, is substituted for oxygen and the cytochrome system. These studies show that the addition of $6.0 \times 10^{-6} M$ NaCN stops the oxidase activity completely and does not diminish the dehydrogenase activity, while the addition of $2.0 \times 10^{-5} M$ selenite stops the dehydrogenase activity completely and does not diminish the oxidase activity. Thus each component has a poison specific for it. The addition of less NaCN or less selenite partially and selectively inactivates one or the other of the components.

These observations show that the oxidation of succinate to fumarate by the beef heart extract proceeds in at least two steps. Two different enzymes are involved, which act sequentially. If the view is correct that in such a system the speed of the slower step determines that of the overall reaction (in this case the rate of oxygen consumption), and if μ values are associated with enzyme-catalyzed steps, then we may expect it to follow that (1) the complex enzyme system, as extracted from beef heart, should yield a μ value characteristic of the particular step which is the slower. (2) By partially poisoning the other (faster) component of the enzyme system, a different μ value corresponding to this now slower component should be obtained. (3) This shift in μ should come abruptly with increasing concentrations of the poison. (4) The μ value should shift back to the original, if both components are

poisoned such that the original slow step is again made the slower. (5) A μ value of about 16,000 should be obtained when the cytochrome-cytochrome oxidase component, which contains catalytically active iron, is poisoned sufficiently to make this step the slow step.

An investigation was undertaken by the writer, in collaboration with Dr. Hadidian, to determine whether these deductions could be verified experimentally. All of the five propositions have been tested and the results have been found to conform to the predictions.¹⁷

Fig. 11 shows reaction velocity curves at different temperatures for a typical

FIGURE 11. Reaction curves for a single experiment with unpoisoned enzyme at different temperatures. The horizontal line indicates the points at which velocities were measured. From Hadidian and Hoagland.¹⁷

experiment with the unpoisoned enzyme extract. The horizontal line indicates the points at which the slopes of the curves were determined as a measure of the velocities. Fig. 12 shows Arrhenius plots in a single experiment with varying concentrations of NaCN. The upper curve yields a μ of 11,000 calories for the normal system. Cyanide added, up to a critical amount, slows the rate at each temperature but does not change the μ , as may be seen by the constancy of slope of the upper two curves. Above this critical amount of cyanide the μ shifts to approximately 16,000 calories (*i.e.*, 15,800 calories). Fig. 13 shows Arrhenius plots of a number of similar experiments on normal and cyanide-poisoned enzyme systems, demonstrating that the critical shift from 11,000 calories, presumably the activation energy of the succinodehydrogenase step, to 16,000 calories for the cytochrome oxidase step occurs at a cyanide concentration somewhere between 1.2×10^{-7} and 1.8×10^{-7} M. In this figure individual experiments have been brought together by shifting the lines vertically to the abscissa. Each symbol represents a different experiment.

Fig. 14 shows what happens when one adds selenite, the dehydrogenase specific poison, to our enzyme system which has already been slowed with sufficient cyanide to yield a μ of 16,000 calories. In this case the μ shifts *back again* from 16,000

FIGURE 12. Arrhenius equation plot of a single experiment on normal and cyanide-poisoned enzyme. From Hadidian and Hoagland.¹⁷ ○ : $\mu = 11,000$; □ : $\mu = 11,000$; △ : $\mu = 15,800$.

FIGURE 13. Arrhenius equation plot of a group of experiments on normal and cyanide-poisoned enzyme. Individual experiments have been brought together by shifting the lines along the ordinate. Each symbol represents a different experiment. From Hadidian and Hoagland.¹⁷ I : $\mu = 11,200$; II : $\mu = 11,400$; III : $\mu = 16,000$; IV : $\mu = 16,000$.

calories to that of the unpoisoned system (11,200). This clearly results from making the dehydrogenase step the relatively slower of the two.

Fig. 15 is a massed plot for the experiments showing the two different μ values, and it should be compared with Fig. 10 showing similar μ values for brain-wave frequencies in advancing general paresis. In Fig. 15 the mean heavy lines are drawn by eye through the data for the respective μ values as indicated; the lighter lines fanning out from these heavy lines are for ± 200 calories around the means.

FIGURE 14. Arrhenius equation plot of a group of experiments on enzyme poisoned with cyanide and with cyanide plus selenite. From Hadidian and Hoagland.¹⁷ I : $\mu = 16,000$; II : $\mu = 11,400$.

FIGURE 15. Composite massed plot for the enzyme experiments described in the text (compare with Fig. 10). Mean heavy lines are drawn by eye through the data; the lighter lines fanning out are for ± 200 calories around the means.

From these experiments it thus appears that the two frequently recurring μ values of approximately 11,000 calories and 16,000 calories for biological rates are due to the fact that succino-dehydrogenase and the cytochrome system respectively are frequently rate-limiting bottlenecks or master reactions. What reaction 8,000 calories, which among other things is the μ for normal alpha brain-wave frequencies, corresponds to, remains to be determined.

From the foregoing discussion one might be misled into taking the view that some sort of constant and invariable relation exists between μ value and enzyme specificity, not unlike the specificity existing between band spectra and substance specificity. Unfortunately no such clear-cut relation as this exists as the following experiments by Hadidian and Hoagland show. As was mentioned under item (d) above, the oxidation of *p*-phenylenediamine catalyzed by the beef-heart extract does not involve the dehydrogenase component but only the cytochrome system. Under these circumstances shall we get a μ value of 16,000 calories? The answer is that we do not. Fig. 16 shows an Arrhenius plot of two typical experiments yielding a μ

FIGURE 16. Arrhenius equation plot for oxidation of *p*-phenylenediamine. $1 \times 10^{-4}M$ *p*-phenylenediamine and 0.5 ml enzyme. ● = determinations made the day of preparation of enzyme. ▲ = determinations made the following day. $\mu = 9,500$ calories. From Hadidian and Hoagland.¹⁸

of 9,500 calories. Thus we see that with a substrate as different from the succinate as is *p*-phenylenediamine, a different energy of activation is involved, even though the same oxygen-activating enzyme system is presumably functioning in both cases.

We may poison the cytochrome system completely with cyanide so as to stop all oxygen uptake and then substitute for it an artificial oxygen carrier, such as the dye cresyl blue, which Stotz and Hastings⁴⁹ have shown to be especially efficient for this purpose. Fig. 17 shows oxygen consumption curves for the normal reaction and for the reaction in which cresyl blue has been substituted for the completely inhibited cytochrome oxidase system. In our dye-substituted system the dehydrogenase step is functioning, but in conjunction with cresyl blue and not with the cytochrome system. What μ values will we get by making one or the other of these steps slow ones? The simplest way to make one or the other of these components limiting, is to compare μ values for experiments in which, on the one hand, we have reduced the amount of the enzyme extract containing the dehydrogenase with, on the other hand, μ values obtained from experiments involving reduced amounts of added cresyl blue. Fig. 18 shows plots in which the dehydrogenase is thus made the limiting factor. In these experiments so much cresyl blue was

FIGURE 17. Oxygen consumption curves for the normal and the dye-substituted reactions. ● = normal: $6.0 \times 10^{-5}M$ succinate, 0.5 ml enzyme. ▲ = dye-substituted: $5.0 \times 10^{-6}M$ cresyl blue, $1.0 \times 10^{-5}M$ cyanide, $6.0 \times 10^{-5}M$ succinate, 0.5 ml enzyme. From Hadidian and Hoagland.¹⁸

FIGURE 18. Curve I. Arrhenius plot for oxygen-consumption curves using dye-substituted enzyme as described in the legend to Fig. 17. Curve II. Arrhenius plot using one-tenth as much enzyme but the same amount of cresyl blue. From Hadidian and Hoagland.¹⁸

present that its further increase did not accelerate the reaction. The μ (curve I) is 18,500 calories and is presumably associated with succino-dehydrogenase which, when working normally with the cytochrome system, yields a μ of 11,200 calories. That 18,500 is the μ for the dehydrogenase working sequentially with cresyl blue is

further borne out by the fact that with one-tenth as much enzyme extract we obtain, in curve II, the same μ despite a great lowering of the reaction velocities. Fig. 19 shows a μ of 22,300 calories obtained by reducing the relative amount of cresyl blue in comparison to the enzyme concentration. This evidently is the activation energy of our artificial catalyst under the conditions of these experiments.

FIGURE 19. Arrhenius plots for experiments with low concentrations of cresyl blue, thus making it the limiting factor. Curve I. $6.0 \times 10^{-5}M$ succinate, $1.0 \times 10^{-5}M$ cyanide, $5.0 \times 10^{-7}M$ cresyl blue (one-tenth as much as in Fig. 18). $\mu = 22,000$. Curve II. $6.0 \times 10^{-5}M$ succinate, $1.0 \times 10^{-5}M$ cyanide, 0.5 ml enzyme, $2.5 \times 10^{-7}M$ cresyl blue. $\mu = 22,300$, i.e., the μ is unchanged when the very small amount of cresyl blue is halved. From Hadidian and Hoagland.¹⁸

These results suggest that an energy of activation is associated, not with the enzyme as a simple chemical entity, but with the particular reaction step involving it as catalyst. Enzymes are, in general, large protein molecules which may be catalytically active at any one of several points, depending on experimental conditions. Thus the same chemical entity might, by functioning differently, yield correspondingly different μ values. It is, of course, also true that our succinate-fumarate enzyme system may contain other steps acting sequentially in addition to succino-dehydrogenase and cytochrome-cytochrome oxidase. There may be several cytochromes with their oxidases acting sequentially. The cytochrome-c reductases recently reported by T. R. Hogness at the University of Wisconsin symposium may also render this system far more complex than is indicated by our simple paradigm. From such a complex system we should expect a number of μ values to emerge with manipulation. It is thus especially interesting that in the simple, aqueously extracted enzyme we get 11,200 calories and 16,000 calories, clearly indicating respectively succino-dehydrogenase and the cytochrome system as they normally function *in vivo*.

The fact that we cannot speak of the activation energy of an enzyme as we can of the absorption spectrum of a substance need not militate against the ultimate usefulness of this concept. It is clear that throughout a vast array of cell systems the same substrates, *e.g.*, glucose, are broken down through identical steps by enzymes specific for each step. The μ value appears to be the only key at the present time to the chemical pacemaker, which, as in the case of general paresis in man, may shift under pathological conditions. As yet no work has been attempted to correlate the significance of this shift with definite symptomatology. Would it be possible to prevent the shift from 8 to 11 to 16 thousand calories by chemotherapy or other forms of treatment? Would prevention of such a shift of μ be correlated with amelioration of psychiatric symptoms? These and many other questions await investigation.

TIME AND CHEMICAL KINETICS

Some years ago the writer became interested in the problem of physiological time in relation to the chemical pacemaker concept. We all possess a subjective appreciation of duration. Even when asleep our time sense continues to function, since some persons can waken themselves within a few minutes of a predesignated time. However, as this subjective or private time is variable, man has created for himself a public time scale based on the regular cyclic properties of the solar system.

Since clock time depends on relative motion, we might ask ourselves what is the source of motion determining our private or physiological time? One thing that might be considered would be molecular motions involved in steady-states maintained by continuous oxidations of foodstuffs by living tissues. Could, let us say, continuous oxidations in the brain constitute a sort of "chemical clock" from which our basic conceptions of duration are derived?

If psychophysiological time is determined by chemical kinetics, raising the internal body temperature should accelerate the reactions, thus making more physiological time pass in a given interval of clock time than would normally be the case. If, let us say, two minutes of subjective time were thus to pass in one minute of clock time we would say that time was dragging; on looking at the clock it would be slower than we think it should be.* Lowering the temperature, on the other hand, should have an opposite effect, making clock time seem to pass faster, since the slowed biochemical rates are measured as reciprocal clock times.

An opportunity to test this hypothesis presented itself in the winter of 1932 when my wife chanced to fall ill with influenza and had a temperature of nearly 104° F. I accordingly asked her to count to sixty at a speed she believed to be one per second without telling her why. As a trained musician she has a good sense of duration. This count was repeated thirty or forty times in the course of her illness; her speed of counting was measured with a stopwatch, and her temperature recorded each time. Not only did she unknowingly count faster at higher than at lower temperatures but her data conformed well to the Arrhenius equation relating chemical velocities to temperature. On the strength of this I repeated the experiment with several volunteer subjects given artificial fever by diathermy, and later I discovered some published data by François on the frequency of tapping a prescribed rhythm at different body temperatures. All of these data when grouped together not only conformed to the Arrhenius equation but yielded a temperature characteristic, or μ value, of 24,000 calories (see Fig. 20)—a value of the order of magnitude reported in several studies for biological oxidations.

These results, which were published in 1933,²⁵ are consistent with the view that our sense of duration, other things being equal, acts as if it were linearly proportional to the speed of some underlying chemical master reaction.

Now it is well known that some living organisms can recover after being subjected to the very low temperatures of the liquefied gases such as air, hydrogen and helium. For these organisms time, at these reduced temperatures, must pass at a greatly accelerated speed if we are right in regarding private time as a by-product of chemical kinetics. Since life and its concomitant ageing processes is a series of chemical events proceeding irreversibly toward death, these temperatures must essentially stop ageing processes. Such organisms are, for all intents and purposes, *projected forward into the future* at these low temperatures. A stay of a century at -270° C, the temperature of liquid helium, with subsequent warming and recovery, would, if it were possible to effect, be precisely equivalent to projecting the organism forward a century into the future—a sort of Wellsian time machine idea.

* It is interesting to note that in "Allgemeiner deutscher Bier-Komment," Chapter II, Part 3 ("Tempus"), p. 27, it is stated:

"Während der Kneipe wird die Zeit nach Bierminuten gerechnet. 5 Bierminuten 3 Zeitminuten."

FIGURE 20. Temperature characteristic for the human time sense. Arrhenius plot for the effect of internal body temperature on the frequency of subjectively counting seconds and tapping proscribed rhythms for naive subjects. For discussion see text. From Hoagland.²⁵

Professor B. J. Luyet, who has made a number of contributions to the field of low-temperature effects on organisms, has recently reviewed with Gehenio³⁷ the subject of life and death at low temperatures. Their review shows that some 120 studies have demonstrated that a variety of small organisms can withstand the temperature of the liquefied gases. These include some bacteria, protozoa, plant cells and a few metazoans. The procedure in general involves rapid chilling and warming so as to vitrify the organisms and not permit their water to crystallize. Crystallization of water takes time and colloidal solutions are slower to crystallize than others. The crystallization range according to Luyet extends for only some 30-40° below zero centigrade. Rapid passage through this range is, for most organisms, essential if they are to survive extremes of chilling. Moreover, the length of time spent at these low temperatures usually, as we would expect, has no effect on the percentage of revivable organisms. Organisms of more than a millimeter or so in size cannot survive this treatment, since heat cannot be conducted from and to their interiors fast enough on chilling and warming to prevent internal crystallization and death.

It recently occurred to me that while it is thus not possible to project a mammal into the future it might, nevertheless, be possible to project his offspring provided that one could vitrify and later recover fertile mammalian sperm. Such a result might be interesting in the future if social sanctions ultimately permitted its human application and its value in connection with the storing of sperm of prize animals to renew deteriorated stock generations after the donor's death is obvious.

On examining the literature we found that Luyet and Hodapp⁶ had successfully vitrified and revived an appreciable number of frog sperm after removing some of their water content by plasmolysis with hypertonic sucrose solutions. They were, however, unable to revive any rat sperm. Shettles⁴⁶ in 1940, in the course of a study of the physiology of human sperm, had been able to vitrify and revive a few per cent of seminal human sperm immersed in capillary tubes in the liquefied gases and later rapidly warmed.

Dr. Pincus and I have confirmed Shettles' findings and extended them. We have been able to revive as many as 67 per cent of human sperm after exposure to liquid nitrogen at a temperature of -195°C .^{33a, 33b}

We do not know how long sperm would remain viable at -195°C but we would expect them to do so indefinitely. We have kept human sperm samples stored in dry ice after vitrification in liquid nitrogen for four months, and found no decline in the

per cent motile on warming, as compared to samples kept at the low temperature for only a few minutes.

Human sperm withstand vitrification and revival better than do those from other mammals that we have examined. Our preliminary experiments with sperm from rat, mouse, guinea pig, rabbit and bull yielded completely negative results. We accordingly decided to investigate systematically rabbit sperm. We have studied sperm samples from the vas deferens of 27 rabbits and also 4 samples of ejaculated rabbit sperm. Luyet and Hodapp were unable to revive frog sperm smeared in films on mica and dipped in liquid air without first plasmolyzing them. After 3 minutes of plasmolysis in 2*M* sucrose solution, about 40 per cent of their frog sperm ceased motion, but the remainder survived immersion in liquid air if followed by very rapid warming. These revived sperm were motile as long afterwards as were controls.

We have found that this same procedure does not permit any revival of mammalian sperm just described. Positive results have been obtained by us only as follows: Occasionally we have had approximately 0.1 per cent revival of bull and of rabbit sperm after liquid-nitrogen immersion by pretreating them for several minutes with Ringer solution of from 1 to 2 times isotonicity containing double the normal amount of Ca. Very occasionally we have had a comparable yield of rabbit sperm after plasmolyzing for 5 to 10 minutes in a solution of 5 times the normal Ringer concentration. Our best, consistently reproducible, results on recovery of motile rabbit sperm after immersion at -195°C , have been obtained by first drying thin smears of otherwise untreated vas sperm nearly to completion on Cellophane in air. These, after the chilling, yield from 0.1 per cent to as much as 1.0 per cent motile sperm when rapidly warmed. Pretreatment of rabbit sperm for from 2 to 10 minutes with a solution made up of 0.01*N* butyric acid in 3-4 times the normal Ringer or serum concentration also yields positive results to the extent of about 0.1 per cent recoverable motile sperm after liquid nitrogen. All of the plasmolyzing solutions that are effective produce complete immobilization on their own account, but this is reversible when the sperm are put in isotonic Ringer serum or glucose phosphate.

We are continuing our experiments and hope that, as in the case of human sperm, we may be able to augment the viable rabbit sperm recovered from liquid nitrogen, from one per cent to a value available for practical artificial insemination. This would make possible further experiments which may be of practical value to animal husbandry in ultimately permitting the storage of the sperm of prize animals for the fertilization of offspring generations after the donor's death. It is startling to consider this aspect of physiological time in relation to human societies if social sanctions ever were to permit women to choose to have children by great men of past generations!

The Colloid Chemistry of Purified Viruses*

MAX A. LAUFFER AND W. M. STANLEY

Department of Animal and Plant Pathology of The Rockefeller Institute
for Medical Research, Princeton, N. J.

The vast field of virus research was opened in 1898 when Beijerinck,¹⁰ after having apparently independently repeated Iwanowski's⁸⁰ discovery of 1892 that juice from plants diseased with tobacco mosaic remained infectious after passing through a porcelain filter, realized that the virulent agent differed from ordinary bacteria and described it as being a "contagium vivum fluidum." Since that time numerous virus diseases have been recognized. As is discussed in more detail in an earlier volume of this series,⁸⁶ one of the many quite diverse ideas which developed gradually throughout the subsequent years was that the agents responsible for these diseases are not fluids but discrete particles,^{1, 21} usually of submicroscopic dimensions, of materials consisting largely of protein. This point of view was finally substantiated in 1935 when a crystalline protein possessing all the properties of tobacco mosaic virus was isolated by means of chemical precipitation from the juice of mosaic-diseased tobacco plants.⁹¹ This protein has been shown to be in chemical combination with a nucleic acid resembling yeast nucleic acid and is, therefore, a nucleoprotein.^{3, 57, 103} Its chemical composition and physical characteristics are quite definite and specific. It gives the usual protein color reactions, is precipitated by the usual protein-precipitating agents, has characteristic heat and pH stability ranges, and is denatured under certain definite conditions. Very dilute solutions give a

* Much of the material discussed in this chapter has been reviewed previously in several completely documented articles.^{52, 95, 97, 98}

specific precipitin reaction with antiserum to the protein. The protein is insoluble at its isoelectric point and in 20 per cent ammonium sulfate solutions. It crystallizes in definite needle-shaped crystals in the paracrystalline or mesomorphic state, visible only with the microscope.⁹¹ The nucleoprotein was found to possess an unusually high sedimentation rate,²² and, based on this property, a method of isolation and purification by high-speed centrifugation was developed.¹¹¹ The latter means proved to be particularly useful in isolating viruses that are too unstable to undergo the more rigorous chemical treatment. By one or the other of these two techniques, the viruses of tobacco mosaic,⁹¹ aucuba mosaic,⁹³ enation mosaic,³ rib-grass mosaic,³⁴ tobacco ring spot,¹⁰⁴ latent mosaic of potato,⁶⁰ cucumber mosaics 3 and 4,^{4, 36} tomato bushy stunt,^{5, 49} tobacco necrosis,⁷⁹ alfalfa mosaic,⁸¹ influenza,¹⁶ foot-and-mouth disease,³¹ Shope rabbit papilloma,⁸ equine encephalomyelitis,¹⁰⁹ and mouse encephalomyelitis,²⁶ the elementary bodies of vaccinia,²⁰ and certain bacteriophages⁷² have been isolated in the form of materials of high molecular weight consisting largely of protein and in some instances obtainable in the crystalline state.

FIGURE 1. Paracrystals of tobacco mosaic virus protein. (X 675). (From Stanley.⁹⁵)

The question naturally arises whether these nucleoproteins are actually the viruses or merely materials contaminated by the virulent agents. The answer has been worked out in greatest detail in the case of tobacco mosaic virus, and all of the evidence at present available indicates that this virus nucleoprotein molecule is actually the active disease-causing entity. The virus protein isolated from many different batches of diseased Turkish tobacco plants and from other plant species infected with the virus possesses the same chemical, physical, biological, and immunological properties.⁵⁹ This protein is capable of infecting other plants, will multiply in them, and can be isolated from such diseased plants. There is no reason to believe that the protein is not pure, for its chemical, physical, biological, and immunological properties remain unchanged following fractionation of the protein by various procedures.⁹⁴ The preparations of the material are completely homogeneous with respect to electrochemical behavior.²² It was found impossible to demonstrate the presence of an impurity in such preparations even by the sensitive precipitin and anaphylactic tests. It has never been found possible to separate the virus activity from the protein by any one of several procedures. The ultraviolet light absorption spectrum of the protein agrees essentially with the destruction spectrum of virus activity.⁵⁴ The pH stability range of the protein was found to coincide with that of virus activity.^{95, 108} Partial or complete denaturation of a preparation by each of

several procedures was found to result in a corresponding loss of virus activity.⁸² Finally, it is possible not only to inactivate and reactivate the virus protein, but also to demonstrate that the inactivation and reactivation are accompanied by simultaneous changes in the structure of the protein molecule.⁸²

It was evident as early as 1916, when Allard found that tobacco mosaic virus passed through a Berkefeld filter but was held back by a Livingstone atmometer porous cup, that the tobacco mosaic virus consisted of particles of dimensions which fall within the colloidal range.¹ Subsequent measurements of the filtration,^{21, 106} sedimentation,⁹ and diffusion of tobacco mosaic virus in unpurified and in semi-purified preparations substantiated this conclusion completely. When plant juice containing tobacco mosaic virus was found to show stream double refraction, it was concluded that the particles of the virus or of something regularly associated with it are rod-shaped bodies.¹⁰⁵ Subsequent studies have shown that several, but by no means all, other viruses are also rod-shaped.^{5, 50, 51} The interpretation of the properties of colloidal systems containing extremely anisometric particles presents a real challenge to the colloidal chemist, whereas the interpretation of the behavior of essentially spherical colloidal particles is a much simpler matter. Therefore, in considering the colloidal chemistry of viruses, it is natural to divide them into two general groups: rod-shaped viruses and essentially spherical viruses. Included in the former are tobacco mosaic virus and its many strains, the latent mosaic of potato virus, and two cucumber mosaic viruses. The latter group includes the viruses of tomato bushy stunt, tobacco necrosis, and alfalfa mosaic, and most of the viruses causing diseases of animals that have thus far been studied sufficiently to permit classification.

Rod-shaped Viruses

Tobacco mosaic virus has been studied more thoroughly than any other representative of the rod group. From a knowledge of its general colloid-chemical behavior, the properties of the other rod-like viruses can usually be inferred. Except when otherwise stated, therefore, the immediately ensuing discussion refers to tobacco mosaic virus. One of the most striking physical characteristics of this ma-

FIGURE 2. Doubly refracting stream of a tobacco mosaic virus solution photographed between crossed Polaroid plates. (From Lauffer and Stanley.⁵²)

terial is its ability to exhibit strong double refraction of flow. The phenomenon was first observed by Takahashi and Rawlins¹⁰⁵ with the juice of mosaic-diseased tobacco plants; and since the isolation of the virus in the form of a nucleoprotein, the phenomenon has been studied in many laboratories.^{3, 7, 32, 41, 42, 51, 61, 65, 80, 105} Double refraction of flow could be due to the orientation of rod-like particles, to the orientation of plate-like particles, or to the photoelastic effect. Takahashi and Rawlins¹⁰⁵ eliminated the second possibility by showing, by a method described by Freundlich, that the optic axis of the entire stream of virus flowing from a capillary is in the direction of the flow. The third possibility was eliminated by the authors,⁵¹ who showed that double refraction persists in a stream of virus for a considerable time after strains due to flow have ceased. According to the theory of Wiener, this double refraction of flow could be due to the orientation of either anisotropic rods (intrinsic double refraction) or isotropic rods of refractive index different from that of the dispersion medium (morphic double refraction). Intrinsic double refraction may be positive or negative; morphic rod double refraction must always be positive. The stream double refraction of tobacco mosaic virus is positive, and it was found to decrease markedly as the index of refraction of the solvent was allowed to approach that of the virus, indicating that at least a considerable fraction of the birefringence is morphic.⁴² This conclusion is entirely consistent with the observation that dried films of the virus show very much less double refraction than wet films.⁷ The double refraction of flow of virus solutions increases as the isoelectric point is approached from either side.⁴¹ It is thought that this is caused by linear aggregation of the virus particles.

The Kerr electro-optical effect of tobacco mosaic and two other viruses has been studied in the authors' laboratory, and it was found that the electrical double refraction

FIGURE 3. Double refraction, expressed as wave length displacements per centimeter, of various concentrations of tobacco mosaic virus at pH 6.4 plotted as a function of the strength of an alternating electric field of 60 cycles. (From Laufer.⁴³)

tion in an alternating field of 60 cycles was negative for weak electrical fields but became positive for stronger fields.⁴³ The inversion point between positive and negative double refraction was found to vary with the concentration of the virus, its age, and the hydrogen ion concentration. In general, modifications of the virus solutions which cause an increase in the forces of attraction between particles were accompanied by an increase in the negative effect and by an inversion point at higher field strengths. Analogous inversions of the sign of electrical double refraction were observed by Norton⁷³ and by Mueller⁶⁹ in bentonite sols. In this case it was found not only that the field strength corresponding to the inversion point decreased upon dilution of the colloid, but also that it decreased when the frequency of the alternating field was increased. In this case, too, a correlation between particle interaction and the magnitude of the negative component was observed. Mueller and Sakmann,⁶⁹ therefore, suggested that this component could conceivably be due to the influence of the electrical field on the interaction, so as to cause an anisotropic distribution of particles. Further studies with bentonite carried out in Mueller's laboratory showed that the positive component of the double refraction fluctuated in intensity with twice the frequency of the electric field at low frequencies, but that the fluctuations disappeared entirely at high frequencies. This is an ideal relaxation phenomenon, and it shows that the positive electrical double refraction is probably caused by orientation of the bentonite particles. Professor Mueller has graciously

FIGURE 4. Layered solution of tobacco mosaic virus protein viewed through crossed Polaroid plates, a, and parallel plates, b. (From Lauffer and Stanley.⁵²)

permitted the authors to state that preliminary studies on tobacco mosaic virus made in his laboratories show that the electro-optical properties of the virus parallel those of bentonite in all the respects discussed above. Hence, it seems reasonable to suppose that the explanations advanced to account for the electro-optical properties of bentonite also apply to tobacco mosaic virus.

Bawden *et al.*^{3, 7} observed that, in relatively concentrated solutions of tobacco mosaic virus, a liquid crystalline phase separates in the form of micro tactoids and settles to the bottom of the solutions. This behavior is analogous to that described previously by Zocher and Jacobsohn for vanadium pentoxide sols.¹¹³ The pellets obtained by ultracentrifuging solutions of the virus are also liquid crystalline.⁴² It

is evident that these liquid crystalline materials are composed of rather poorly defined mosaics of small volumes, in each of which all of the virus particles are oriented parallel to one another.^{3, 51} Best¹³ has found, further, that the virus separates from 0.4*M* solutions of $(\text{NH}_4)_2\text{SO}_4$ at pH 5 in the form of long, very thin fibers showing positive double refraction. Bernal and Fankuchen¹¹ observed that, when solutions of tobacco mosaic virus are evaporated under certain conditions, films of dry or semi-dry protein are obtained in which all the particles are lined up parallel. These films will swell in water and finally disperse, but in ammonium sulfate or in buffered solutions they swell to equilibrium positions which are functions of the ionic strength and the pH.

Attempts have been made by Levine⁵⁶ and by Langmuir³⁸ to account for these phenomena in terms of long-range interparticle forces. It was pointed out that it follows from the Debye-Huckel theory that the net effect of the electrical charges on colloidal particles, considered in conjunction with their necessarily present gegenions, is attraction at long distances and repulsion at short distances. In such a case, one would expect to have a potential energy minimum at some definite distance from each particle, as is illustrated in Fig. 5. If the depth of the potential trough is greater than kT , this position ought to determine the distance between particles in an equilibrium gel. Furthermore, although the theory has not been

FIGURE 5. Potential energy plotted as a function of the distance between two charged colloidal particles surrounded by ion atmospheres. (From Bernal and Fankuchen.¹¹)

worked out in detail for such a case, the occurrence of a potential trough would provide a mechanism for maintaining a perfectly parallel orientation of rod-like particles.

The applicability of these theoretical considerations to the case of tobacco mosaic virus protein has been tested in a qualitative sense by Bernal and Fankuchen.¹¹ For the case of spherical particles, Levine showed that the depth of the potential trough should increase, and the distance of the potential energy minimum from the particle should decrease when the concentration of electrolyte is increased. Bernal and Fankuchen measured the equilibrium distances between virus particles in gels in equilibrium with ammonium sulfate solutions of various concentrations, using x-ray diffraction techniques. Their data are presented graphically in Fig. 6. The curve fitting the data has the shape predicted by Levine's theory, but some of the con-

FIGURE 6. Lateral distance between parallel tobacco mosaic virus rods in an equilibrium gel plotted as a function of the $(\text{NH}_4)_2\text{SO}_4$ concentration. (From Bernal and Fankuchen.¹¹)

stants had to be assigned arbitrarily to make it fit. In any case, the data are in qualitative accord with the theory. A further qualitative test is afforded by the results of Best,¹³ who determined the concentrations of virus at which the liquid crystalline and isotropic phases (see Fig. 4) can coexist. He found that in systems at pH 7 and 30° C the two phases coexist at virus concentrations between 1.4 and 2.2 per cent in the absence of electrolyte and at concentrations between 1.8 and 2.9 per cent in NaCl solutions more concentrated than 0.005*M*. These results would seem to indicate that the equilibrium distance in the oriented phase decreases with increase in electrolyte concentration—a result in qualitative accord with the Levine theory. In view of these results, it seems reasonable to conclude that one can establish a fair case for the existence of long-range intermolecular forces of the Levine-Langmuir type in tobacco mosaic virus systems.

All the properties thus far considered are, of course, a consequence of the anisometric nature of the virus particles. As was pointed out, the stream double refraction of the viruses is that characteristic of rod-like rather than plate-like particles. As will be seen later, the x-ray diffraction patterns of the rod-like crystals of the virus support the interpretation that the virus particles themselves are rod-like bodies and, as final proof, direct micrography with the electron microscope shows that the particles are rod-like.

Many attempts have been made to measure the size of tobacco mosaic virus particles. The most frequently used method is that of ultracentrifugation. The molecular weight, *M*, of a particle may be expressed as a function of the sedimentation velocity in unit centrifugal field, *S*, according to equation (1).

$$M^{2/3} = \frac{6\pi\eta_0 NS \left(3 \frac{V}{4\pi N}\right)^{1/3}}{(1 - V\rho) \frac{f_0}{f}} \quad (1)$$

η_0 is the viscosity of the solvent, *N* Avogadro's number, *V* the partial specific volume of the solute, ρ the density of the solution, and f_0/f the dissymmetry factor or the ratio of the frictional factor the particle would have if it were a sphere to that it actually does have. Bechhold and Schlesinger⁹ were the first to study the rate of sedimentation of the virus in plant juice. Their results, which were based on virus activity measurements, are in good agreement with the results obtained later on the purified protein by Eriksson-Quensel and Svedberg,²² by Wyckoff,^{107, 108, 111} and by the authors.⁴⁴ The latter workers found that the protein isolated and purified by chemical means is quite heterodisperse, whereas that isolated and purified by means of differential centrifugation gives a single reasonably sharp boundary in the ultracentrifuge. Values for the sedimentation constant, *S*₂₀, as low as 174×10^{-13} and as high as 193×10^{-13} cm/sec/dyne/gram have been reported for the centrifugally isolated material. It has been shown recently that the sedimentation constant of the infection principle of the virus agrees within a probable error of 8% with that of the virus protein.⁴⁰ Because of the extremely anisometric character of the virus particles, many difficulties, the most important of which are discussed in the following paragraphs, are encountered in interpreting these sedimentation results.

The validity of the assumption, inherent in Stokes' law, that the sedimenting virus particles are independent of one another has been questioned, especially by Frampton.^{23, 25} The spontaneous formation of liquid crystalline layers of the virus must be due to forces of attraction between particles in moderately concentrated solutions.^{7, 11} The viscosity results of Stanley⁹⁶ and Lauffer⁴¹ indicate that, in virus solutions as concentrated as 1 per cent or perhaps even somewhat less, one encounters interaction between particles. The diffusion results of Neurath and Saum⁷¹ would indicate that such interaction was present in solution more concentrated than 0.5 per cent. The studies of Frampton and Saum,²⁵ who measured the viscosity of the

FIGURE 7. Sedimentation constant plotted as a function of tobacco mosaic virus concentration. (From Lauffer.⁴⁴)

virus with varying rates of shear, show that even in very dilute solutions the viscosity coefficient is not independent of the rate of shear; that is, anomalous viscosity is encountered. These results have led Frampton to conclude that the fundamental assumption of Stokes' law is violated by even very dilute solutions of the virus. A direct experimental approach to this problem was made in the authors' laboratory.⁴⁴ Sedimentation measurements were carried out on preparations of purified tobacco mosaic virus at various concentrations. As is shown in Fig. 7, there is a strong dependence of the sedimentation rate on virus concentration—a relationship which seems to hold even for dilute solutions. This behavior is analogous to that of the linear high polymers. If all the assumptions inherent in Stokes' law were fulfilled by tobacco mosaic virus solutions, such a relationship would not obtain. It is a matter of definition that at infinite dilution suspended particles must be mutually isolated. Therefore, by extrapolating the sedimentation-concentration data to zero concentration, a value of the sedimentation constant for a solution meeting the theoretical requirements can be obtained. The obvious way to extrapolate is simply to extend the straight line which best fits the experimental data. Unfortunately, however, an element of uncertainty attends any projection of this sort.

It seems very probable that the retardation of the sedimentation rate is at least in part a manifestation of the same fundamental attribute of the virus particles as that which is responsible for the anomalous viscosity in concentrated solutions, for the thixotropic nature of concentrated solutions, for the formation of birefringent phases, and for the retarded diffusion in concentrated solutions. As was discussed previously, the latter phenomena can be accounted for in terms of interaction of an electrostatic nature between virus particles. Only virus solutions more concentrated than 1.4 per cent will separate into two phases.¹³ The retardation of the diffusion rate of the virus vanishes upon dilution.⁷¹ The anomalous negative electro-optical behavior, which can be accounted for in terms of interaction, disappears upon dilution.⁴³ These results lead to the expected conclusion that this interaction varies in

some inverse manner with the distance between particles. Viscosity increments imparted by the virus to its solutions are, with a high degree of precision, directly proportional to the amounts of virus added for concentrations up to 0.1 per cent^{24, 41, 52} (Fig. 8). Double refraction of flow is almost exactly proportional to the amount of virus for all concentrations less than 0.5 per cent^{65, 80} (Fig. 9). Both of these behaviors are characteristic of ideal systems, and they support the conclusion that interaction plays a negligible role in virus solutions more dilute than 0.1 per cent. The only apparent obstacle to accepting this conclusion is the fact that even very dilute solutions exhibit anomalous viscosity.²³ However, this can be explained without reference to particle interaction, for Robinson,⁸⁰ by measuring simultaneously double refraction of flow, average orientation of particles, and resistance to flow, was able to account for the anomalous viscosity of very dilute tobacco mosaic virus solutions in a satisfactory manner as being due to the change in the average orientation of mutually independent rod-like particles caused by changing the flow velocity gradient (Fig. 10). Hence, it seems safe to conclude that tobacco mosaic virus solutions as dilute as 0.1 per cent do not depart much from the ideal condition and that the sedimentation constant of the virus in such solutions ought to be very nearly the same as that at infinite dilution. The method adopted above for extra-

FIGURE 8. The relationship between the specific viscosity and the concentration of tobacco mosaic virus. (From Lauffer and Stanley.⁵²)

FIGURE 9. The relationship between virus concentration and stream double refraction, expressed as wave length displacements per centimeter, in a velocity gradient of 3.7 sec^{-1} . (From Lauffer and Stanley.⁵²)

polating the sedimentation-concentration data yields a value for the sedimentation constant at infinite dilution which differs from that for a concentration of 0.1 per cent by less than the error inherent in the measurement. Therefore, in view of the foregoing, it ought to be a reasonable estimate of the true constant at infinite dilution.

FIGURE 10. The relative viscosity of a 0.02% solution of tobacco mosaic virus at 14.4° C. plotted as a function of shear velocity. The points are experimentally found, and the curve calculated from measurements of stream double refraction and angles of isocline by means of an equation derived by Robinson. (From Lauffer and Stanley.⁵²)

A difficulty is encountered in interpreting the sedimentation data of asymmetrical viruses because the frictional coefficient of rod-like particles is very different from that of spheres. The usual method of overcoming this obstacle, the study of sedimentation equilibrium, was found not to yield satisfactory results because of technical difficulties.²² From the ratio of length to thickness of particles it is possible, by making use of equation (2) (Herzog *et al.*,²⁰ Perrin⁷⁵), to calculate a factor, commonly known as a dissymmetry constant, which is meant to correct for the deviation of the frictional coefficient of rod-like particles from the value given by the usual form of Stokes' law.

$$\frac{f}{f_0} = \frac{(a/b)^{2/3}}{\sqrt{1 - (a/b)^2}} \ln \frac{1 + \sqrt{1 - (a/b)^2}}{a/b} \quad (2)$$

where a and b are the minor and major axes of an ellipsoid of revolution. Many attempts have been made to find a relationship between the viscosity of solutions of asymmetrical particles and the relative dimensions of the particles. Polson⁷⁷ has shown that an empirical equation differing only slightly from Kuhn's theoretical one,³⁷ when applied to a great many proteins, yields values for the ratio of particle length to thickness which are in excellent agreement with values obtained by an independent method. Lauffer⁴¹ and Frampton and Neurath,²⁴ using Kuhn's*,³⁷

* Simha⁸⁵ has more recently derived a somewhat different equation relating relative viscosity to particle dimensions. This equation seems to be the most satisfactory yet obtained,⁴⁶ but it was not available at the time the studies on tobacco mosaic virus referred to in the text were carried out.

equation (Eq. 3), estimated the ratio of length to thickness of the virus particles from viscosity data obtained in Ostwald viscometers and obtained a value of about 35:1.

$$\frac{\eta}{\eta_0} = 1 + 2.5G + \frac{G}{16} (a/b)^2 \quad (3)$$

where G is the volume of the dispersed material per cc of solution and $\frac{\eta}{\eta_0}$ is the relative viscosity of the solution. The dissymmetry constant was then calculated by equation (2) and from it, Wyckoff's¹⁰⁷ sedimentation data, and a partial specific volume of 0.73, the molecular weight was estimated by Lauffer,⁴¹ using equation (1), to be about 43×10^6 , corresponding to a particle 430 m μ long and 12.3 m μ in diameter.

It was pointed out that several limitations are inherent in this method. They include the necessity of assuming that hydration and the electro-viscous effect are negligible and that the rod-like particles are randomly oriented in the flowing stream in the viscometer. It was shown experimentally that the electro-viscous effect was of some importance, and it was stated that a considerable degree of orientation of particles should be expected in a capillary viscometer. It was, however, pointed out that these two errors tend to compensate each other, at least partially. Robinson⁸⁰ has emphasized the importance of the orientation of rod-like particles in respect to their contribution to the viscosity of their solutions and has devised a method of studying simultaneously the stream double refraction, the average orientation of particles (angle of isocline), and the viscosity of a solution of asymmetrical particles at various velocity gradients. By means of an approximate equation derived by him involving all these factors, he estimated the relative dimensions of the particles to be about 80 to 1. This method has been very useful in elucidating the nature of the anomalous viscosity of very dilute solutions of tobacco mosaic virus, but the value for the relative dimensions of the virus particles is in poorer agreement with the values derived from independent methods than those obtained by the less elegant method involving the use of Kuhn's equation. This may be due in part to aggregation in the virus preparations used by Robinson, as he suggested, especially since the preparations were obtained by chemical means.

By assuming that the frictional coefficients in sedimentation and in diffusion are the same, an equation expressing the molecular weight as a function of the sedimentation constant and the diffusion constant, D , can be derived (Eq. 4).

$$M = \frac{RTS}{D(1 - V\rho)} \quad (4)$$

where R is the gas constant and T is the absolute temperature. Using this equation, it is possible to calculate the size of particles of any shape from sedimentation and diffusion data. Neurath and Saum,⁷¹ using the method of Lamm, estimated the diffusion constant of the virus to be about 3×10^{-8} cm² per sec. The molecular weight calculated from this value and Wyckoff's sedimentation constant of 174×10^{-13} , using equation (4), is about 60×10^6 . From the sedimentation and diffusion data, Svedberg's dissymmetry factor may readily be calculated, and from it, employing the Herzog-Perrin equation (Eq. 2), the ratio of the dimensions of the rodlike particles may be estimated. This value is 58 for tobacco mosaic virus, corresponding to particles 675 m μ long and 11.6 m μ in diameter. Even if the seemingly reasonable assumption that the particles are essentially mutually independent in the dilute solutions used for the diffusion and sedimentation measurements is granted, a limitation to this method still remains. The assumption that the frictional resistances in diffusion and in sedimentation are the same is strictly valid only if

the orientation of the particles is random in both cases. It is entirely possible that the randomness is disturbed somewhat in the centrifuge, due to an orienting tendency caused by the radial gradient of the centrifugal field and not compensated for by thermal agitation because of the extremely large size of the virus particles.

Mehl⁶⁵ studied the double refraction of flow and the average orientation of particles of tobacco mosaic virus in an apparatus resembling somewhat a Couette viscometer. Following a method due to Boeder,¹⁵ he estimated the rotational diffusion coefficient of the virus to be 25 at 0° C. By substituting this in an expression derived by Kuhn³⁷ relating the rotational diffusion coefficient to the reciprocal of the third power of the length of rod-like particles, he obtained a value of 610 m μ for the length of virus particles.

Ever since the agent was first recognized, tobacco mosaic virus has been the subject of filtration experiments conducted by numerous workers. A painstaking study of many strains of tobacco mosaic virus and of other plant viruses, some of which are symmetrical, was carried out by Thornberry,¹⁰⁶ using the carefully standardized method of Elford. He found that all the viruses which he studied, when diluted with solvents containing nutrient broth, would just pass through filters with an average pore diameter of 45 m μ . Tobacco mosaic virus purified by the modified lead acetate method of Stanley just passed a filter with a pore diameter of 34 m μ . If it is assumed that rod-shaped particles pass through the pores of the filters lengthwise and that the ratio of pore diameter to particle diameter obtained by Elford for symmetrical particles holds for the diameters of the rods, these results would indicate that the diameters of the rods in unpurified samples of tobacco mosaic virus and its related strains fall within the range of 15-22 m μ and that of the purified virus within the range of 11-17 m μ . These dimensions are thus seen to be in agreement with those determined by a variety of other methods. This is true for all the cases investigated by Thornberry, including symmetrical and asymmetrical viruses. Smith and MacClement⁸⁹ did not confirm his results in their earlier experiments, but in their more recent study they found that some tobacco mosaic virus would pass filters with pore diameters as low as 40 m μ . These workers found, moreover, that in an electrical field the tobacco mosaic virus will pass through filters with an average pore diameter of 13 m μ . One may conclude that the probability that the virus particles will squeeze through the pores of the filters is greatly increased by the orientation of the virus particles parallel to the pores by the electric field and by the tendency for the particles to migrate in an electric field.

Langmuir and Schaefer³⁹ found that they were able to adsorb a film of tobacco mosaic virus on a surface containing a monolayer of egg albumin. By an interference method, they measured the thickness of the film to be 12.5 m μ . They interpreted this to be a film one molecule thick of virus particles lying flat on the surface.

Bernal and Fankuchen¹¹ reported studies of the x-ray diffraction patterns of dilute solutions of tobacco mosaic virus, of liquid crystalline solutions, of films of the virus protein obtained by evaporation and designated as wet and dry gels, and of oriented virus crystals. Wyckoff and Corey¹¹² studied the diffraction pattern of crystals and of pellets obtained with the ultracentrifuge. The findings from these two laboratories agree on what Bernal and Fankuchen regard as the intramolecular structure of the material. Bernal and Fankuchen regard the unit which is usually thought to be the molecule as having an internal structure of great regularity, analogous to the structure of crystalline proteins. The patterns which indicate this structure are identical for the protein in all states studied, including solutions, and therefore must define the molecule rather than the crystal. This constancy of internal structure is evidence that the virus particles do not swell in solution. A lateral interspacing of 15.2 m μ is found in the dry gel studied by Bernal and Fankuchen. This spacing becomes wider and wider in wet gels and in liquid crystalline solutions

and disappears in ordinary solutions. It is also found as a lateral spacing in the oriented dry crystals. Hence, it probably represents the closest distance of lateral approach of parallel rod-like molecules, giving an estimate of the diameter of the rod-like particles making up the crystals and films. No analogous regularity of less than 120 m μ could be found in directions other than at right angles to the length of the crystals. Accordingly, Bernal and Fankuchen suggested that, although in the crystals rod-shaped molecules are arranged parallel to one another in hexagonal symmetry with respect to cross-section, there is no intermolecular regularity in the direction of the long axis.

FIGURE 11. The arrangement of the rod-shaped molecules of tobacco mosaic virus protein in the needle-shaped crystals, according to the views of Bernal and Fankuchen. Left, longitudinal diagram showing parallel orientation of particles without intermolecular regularity in lengthwise direction. Right, cross-sectional diagram showing hexagonal intermolecular symmetry. (From Lauffer and Stanley.⁵²)

Various estimates of the size of tobacco mosaic virus particles obtained from combinations of sedimentation with viscosity and diffusion data and from stream double refraction, ultrafiltration, adsorption, and x-ray studies have just been described. The several estimates of the length of the particle cover the range from 430 to 675 m μ , and those of the thickness from 11 to 15 m μ . During the past few years, direct evidence concerning the size and shape of tobacco mosaic and other viruses has been made available through studies conducted in several laboratories with the electron microscope. In general, the conclusions drawn from the indirect measurements have been confirmed. Kausche^{33, 83} and his associates found that his preparations of tobacco mosaic virus consisted largely of rod-like particles 310 m μ in length and about 15 m μ in diameter. Stanley and Anderson¹⁰⁰ found that the dimensions 280 \times 15 m μ predominated in their preparations of the virus. Even though the length of the image of a particle on a developed plate can be measured with an estimated absolute precision equivalent to about 5 m μ , an uncertainty which could easily be of the order of magnitude of ± 10 per cent is inherent in the methods used to determine the magnification factor of the electron-optical system. Hence, the results from these two laboratories are not in disagreement.

Of all the methods that have been used to measure the virus rods, x-ray evidence is capable of yielding the most precise values for the thickness of the rods, and the electron microscope affords the best measure of the length of the rods. In view of this, a rod-like body 300 m μ long and 15 m μ in diameter, with a molecular weight of around 40 millions, can be regarded as a very good model of the predominating particles in a solution of tobacco mosaic virus—at any rate, of the strain currently being investigated in the Rockefeller Institute laboratories. The fact that this model agrees reasonably well with that which was previously proposed from only a consideration of all of the indirect methods shows that, in spite of their many limitations, the various physical means available for estimating the size and shape of anisometric particles are useful tools when cautiously applied.

It has been known for some time that many strains of tobacco mosaic virus exist, and it was first shown in this laboratory that chemically rather similar nucleoproteins

FIGURE 12. Electron micrographs of tobacco mosaic virus particles. (X 35,000).
(From Stanley and Anderson.¹⁰⁰)

could be isolated from plants diseased with various strains.^{91, 93} Recent studies by Knight and Stanley have shown that the nucleoproteins of at least several of these strains differ slightly, but significantly, in amino acid composition.^{34, 36} The stream double refraction studies of the authors⁵¹ and the x-ray diffraction studies of Bernal and Fankuchen¹¹ showed that, in general, the particles of these nucleoproteins had similar shapes. However, the sedimentation results from Wyckoff's^{107, 108, 110} laboratory first suggested that there were minor differences in the sizes of the particles of the various strains. Recent studies have tended to substantiate that indication. Pfankuch, Kausche, and Stubbe⁷⁴ recently isolated several tobacco mosaic virus strains. A comparison of one of their strains, designated Tm 44 by them, with what they considered normal tobacco mosaic virus may serve as an example of how the protein particles can vary from strain to strain. Tm 44 was found to have a higher specific turbidity, twice the specific viscosity per unit concentration, a sedimentation constant greater by roughly 14 per cent, and an electrophoretic mobility at 0° in phosphate buffer at pH 6.9, $s = 0.1$, about 12 per cent less than that of the protein isolated from the normal strain of the virus. In general, these data may be interpreted to mean that the particles of Tm 44 are longer and heavier than those of the normal virus. Knight and Lauffer³⁵ found that the rib-grass strain of tobacco

mosaic virus migrates more slowly in the electrophoresis apparatus than the normal strain. Melchers⁶⁶ and co-workers studied a strain of tobacco mosaic virus isolated by them from tomato plants and called "tomato mosaic virus Dahlem 1940." This material was reported to have a slightly different electrophoretic mobility from tobacco mosaic virus but the same sedimentation constant. However, since they studied the sedimentation of the tomato virus at a concentration of 0.2 per cent and that of the tobacco virus at 0.3 per cent, and in view of the fact that the sedimentation constant of tobacco mosaic virus increases upon dilution, this result, if sufficiently accurate, really means that tomato mosaic virus has a slightly lower sedimentation constant than their normal strain of tobacco mosaic virus. Electron micrographs show that the particles of the tomato mosaic strain are actually only about two-thirds as long as those of the tobacco mosaic strain. Even the particles of the strain which Melchers and his associates consider to be normal tobacco mosaic virus are shown by their electron micrographs to be only 180-190 m μ in length—about two-thirds the value obtained in the other laboratories. If the possibility that this difference is due to uncertainty in the computation of enlargement factors is discarded, the possibility remains that the normal tobacco mosaic virus used by Melchers is really a strain different from the one or ones studied in the other two laboratories. The possibility that there are strains of tobacco mosaic virus which are differentiated by the length of the particles but not by the commonly applied biological tests is not an unreasonable one.

The recognition that strains of tobacco mosaic virus differ in the chemical composition of the nucleoproteins has led to attempts to produce new strains in the laboratory by chemical modification of the normal strains of the virus. Miller and Stanley prepared acetyl, phenylureido, carbobenzoxy, *p*-chlorobenzoyl, and benzenesulfonyl derivatives of the normal strain of the virus.⁶⁸ When the extent of substitution was not carried too far, these chemically modified viruses retained full infectivity. Anson and Stanley² oxidized the S-H groups of tobacco mosaic virus nucleoprotein with iodine beyond the S-S stage without destroying infectivity. However, all these chemically modified viruses reproduced in the host plant to form normal tobacco mosaic virus. Nevertheless, Miller and Stanley⁶⁸ found that biological properties of the derivatives were altered.

Electrophoresis experiments on tobacco mosaic virus were first carried out by Eriksson-Quensel and Svedberg²² using the Tiselius electrophoresis method. They found the material to have an isoelectric point at pH 3.49 and a pH-mobility curve with a slope of 1.23 cm per sec/volt per cm/pH unit in acetate buffers with an ionic strength of 0.02. Although the chemically prepared virus examined was inhomogeneous with respect to the criterion of sedimentation rate, it was found to be homogeneous with respect to that of electrophoretic mobility. This introduces the general question of the homogeneity of tobacco mosaic virus preparations. Further evidence on this question may be gained from a consideration of x-ray diffraction data, centrifugation data, solubility data, and electron micrographs. Because of the degree of perfection of the intermolecular x-ray pattern of dried gels of tobacco mosaic virus,¹¹ it seems likely that the virus particles are of absolutely uniform thickness. The earlier sedimentation studies made in Svedberg's laboratory²² on chemically isolated material indicated a considerable degree of inhomogeneity, but from later studies made on ultracentrifugally isolated virus Wyckoff^{107, 108, 111} concluded that the virus particles were homogeneous. A more recent consideration of the sedimentation behavior carried out in the authors' laboratory⁴⁴ indicates that even ultracentrifugally isolated preparations are not strictly homogeneous with respect to this criterion. Since x-ray data show that the particles are of uniform thickness, the inhomogeneity must be the result of variability in the lengths of the particles. Indeed, electron micrographs show this to be the case.¹⁰⁰ Fig. 13 is a frequency

chart showing the distribution of particle lengths measured from an electron micrograph of tobacco mosaic virus. It may be seen that most of the particles are about 280 m μ long, but that there are some longer and some shorter ones.

FIGURE 13. Distribution of lengths of particles in an ultracentrifugally prepared sample of tobacco mosaic virus. (From Stanley and Anderson.¹⁰⁰)

Another approach to this question of homogeneity is afforded by solubility studies. The early work of Stanley⁹¹ showed that tobacco mosaic virus was insoluble in strong salt solutions and in solutions having acidities near the isoelectric point. Best¹⁴ has shown that many electrolytes will precipitate the virus and that the relative precipitating powers of various electrolytes depend upon the valence and the character of the ions. More recently, Cohen found that the virus can be precipitated in paracrystalline form by small amounts of heparin and other hydrophilic colloids.¹⁷ Loring⁵⁸ attempted a phase rule study of tobacco mosaic virus in ammonium sulfate solutions of constant composition. It is well known that, if a material consists of a single pure substance, it should have a constant solubility, independent of the amount of solid phase in contact with the solvent. Loring's data are shown in Fig. 14. It is plain that the solubility behavior of tobacco mosaic virus protein is not what one would expect of a homogeneous material.

The question of the homogeneity of tobacco mosaic virus is complicated by the tendency of the virus particles to aggregate upon ageing.⁶¹ Wyckoff¹⁰⁷ first observed that, if a freshly prepared batch of tobacco mosaic virus, with a sedimentation constant of about 174×10^{-13} , is allowed to stand in contact with electrolytes for a few days, a second component with a sedimentation constant of about 200×10^{-13} is formed. The authors showed that this behavior could be interpreted quantitatively to mean that virus rods were aggregating end to end to form dimers.^{41, 52} Electron micrographs have confirmed the correctness of this interpretation and have shown that this aggregation can be carried much further than the dimeric stage.¹⁰⁰

The colloid chemical properties of tobacco mosaic virus nucleoprotein are changed completely when the protein is denatured. Denaturation can be brought about by the action of heat,⁴⁹ high pressure,⁴⁸ and chemical agents such as acids, alkalis, urea,^{6, 47, 102} and sodium dodecyl sulfate.⁹⁰ Denaturation by heat, high pressure, and urea has been studied in most detail. In all these reactions, the macromolecular nucleoprotein is broken down by first-order processes into much smaller protein frag-

FIGURE 14. Solubility of tobacco mosaic virus in 0.1 *M* potassium phosphate and 11.18% ammonium sulfate buffer. Curve I at pH 5.6; curve II at pH 6.4. (From Loring.⁵⁸)

ments, with the loss of infectivity and with the separation of nucleic acid from the protein. The separation of nucleic acid by denaturation of tobacco mosaic virus was observed by Bawden and Pirie³ and was recently studied by Cohen and Stanley.¹⁹ The latter found by a combination of sedimentation, diffusion, and viscosity studies that the freshly isolated nucleic acid has an average particle weight of around 300,000 and is highly asymmetric. This decomposes spontaneously to form asymmetric particles of about one-fifth the weight of the original. These can in turn be converted into still smaller fragments by the action of cold alkali. The rate of the thermal denaturation was found to vary with the pH and, contrary to all simple theories, with the reciprocal of the initial virus concentration.^{49, 78} The rate of denaturation in urea was also found to vary with respect to those two variables, in addition to electrolyte concentration and urea concentration.⁴⁷ Miller found that phenylureido, carbobenzoxy, *p*-chlorobenzoyl, and benzenesulfonyl derivatives of the virus denatured more slowly in urea than did normal and acetylated virus.⁶⁷ The denaturation in 6*M* urea was found to proceed faster in the cold than at room temperature and also faster at 45° C than at room temperature.^{6, 47, 102} An explanation for this very unusual behavior has been advanced, and evidence has been obtained which tends to substantiate the theory.⁴⁷

Tobacco mosaic virus, in common with the elementary bodies of vaccinia, with tomato bushy stunt virus, and with other viruses, may be inactivated by irradiation with ultraviolet light, x-ray, alpha rays, and gamma rays.^{27, 55, 64} Surviving infectivity appears to be an exponential function of the amount of radiation. This result is generally interpreted to mean that a single hit is sufficient to cause the destruction of the infectivity of a virus particle. According to current concepts, an atom which is hit by a unit of suitable radiation is ionized. Thereupon, the molecule containing that atom becomes extremely reactive, and if that molecule is a virus particle the loss of infectivity may result. It has been observed that the amount of inactivation due to the irradiation of tobacco mosaic virus is greater the higher the net positive charge of the virus.⁶⁴ This result has been interpreted to mean that viruses may also become inactivated by secondary reactions following the ionization of solvent molecules.⁶⁴ From the amount of radiation, it is possible to calculate the density of ions or ion clusters produced. Then from the fraction of virus particles inactivated at a given ion density, it is possible to compute the size of the target a virus particle affords. Such a target size really represents the portion of a virus particle labile to radiation. The target sizes for most plant viruses seem to be somewhat though not greatly less than the known particle sizes.^{27, 55}

Spherical Viruses

Although the colloidal properties of tobacco mosaic virus illustrate what one can expect, in general, for most of the rod-like viruses, they do not apply to all viruses.

The colloid-chemical behavior of the spherical viruses is much simpler and much more easily understood. Indeed, the answer to such important questions as whether or not virus particles are molecules in the strictest sense of the term will probably have to be sought from studies carried out with the spherical viruses. As indicated previously, many virus nucleoproteins with essentially spherical particles have been isolated, but of this whole group only the elementary bodies of vaccinia and the tomato bushy stunt virus have been subjected to detailed colloid-chemical study. Several very interesting colloid-chemical experiments have been carried out with the former.^{28, 76, 84, 87, 88} However, this virus is somewhat more complex than most viruses and, hence, the tomato bushy stunt virus is probably more typical of the spherical viruses as a class. Tomato bushy stunt virus was obtained by Bawden and Pirie⁵ and later by Stanley⁹⁹ in the form of a nucleoprotein which crystallizes from ammonium sulfate solutions in beautiful dodecahedra. Prisms and rhombohedra may be obtained when the crystallization is induced by certain hydrophilic colloids.^{17, 18} Bushy stunt virus has a nucleic acid content of about 17 per cent, a value about three times that of tobacco mosaic virus. This is perhaps the most conspicuous chemical difference that has as yet been established between the two viruses.

FIGURE 15. Crystals of bushy stunt virus protein. (From Stanley.⁹⁹)

Bushy stunt virus preparations do not show double refraction of flow; pellets of the virus obtained upon high-speed centrifugation are not liquid crystalline, and the virus itself crystallizes in the cubic system. All of these facts point to the conclusion that the particles of bushy stunt virus are spherical or nearly so. More exact information concerning the size and shape of the virus particles has been derived from

sedimentation equilibrium,⁶² sedimentation velocity,^{44, 53, 62} diffusion,⁷⁰ x-ray diffraction,^{11, 12} and electron microscope studies.¹⁰¹

Sedimentation equilibrium studies were conducted by McFarlane and Kekwick.⁶² An analysis of their published data shows that there is only a slight drift in the values calculated for the molecular weight at various distances through the equilibrium column. This is an indication that the particles of bushy stunt virus are reasonably homogeneous, although it is not a particularly sensitive criterion of that attribute. Taking the specific volume to be 0.739, they calculated the mean molecular weight from three equilibrium runs to be 7.6×10^6 .

FIGURE 16. Sedimentation equilibrium experiment on bushy stunt virus. (From McFarlane and Kekwick.⁶²)

McFarlane and Kekwick⁶² also made a series of sedimentation velocity experiments on bushy stunt virus dissolved in various buffers covering the pH range from 2.4 to 8.7. The sedimenting boundaries were found to be quite sharp, again indicating a reasonable degree of particle homogeneity. An average of eleven determinations on one preparation of virus gave a value of 146×10^{-13} for the sedimentation constant. On the assumption that the virus particles are unhydrated spheres, one can calculate a molecular weight of 8.8×10^6 from this value of the sedimentation constant. This calculation may be carried out by using equation (1), setting f_0/f equal to 1. The sedimentation velocity of this virus was also studied in the authors' laboratory.^{44, 53} It was shown that the sedimentation rate, unlike that of tobacco mosaic virus, was essentially independent of virus concentration. An average value of 132×10^{-13} , with a standard deviation of about ± 3 per cent, was calculated for the sedimentation constant from almost fifty measurements made on several preparations of the virus. This value for the specific material being studied was confirmed in four other laboratories, including McFarlane's, and is, therefore, almost certainly correct within 1 or 2 per cent.* By assuming that the virus particles are unhydrated spheres, and by using equation (1) as previously described, one can calculate the molecular weight from a sedimentation constant of 132×10^{-13} to be 7.4×10^6 . Both this value and that of 8.8×10^6 , obtained by McFarlane and Kekwick, agree reasonably well with the molecular weight calculated from sedimentation equilibrium, 7.6×10^6 .

The molecular weight of bushy stunt virus has also been evaluated from a combination of sedimentation with diffusion data, using equation (4). Diffusion studies were carried out by Neurath and Cooper,⁷⁰ using the Lamm Scale procedure. A value of 1.15×10^{-7} was obtained for the diffusion constant, corrected to water at 20° C. If this value for the diffusion constant is used in conjunction with the authors' sedimentation data, a value of 10.6×10^6 may be calculated for the molecular weight.

* The lower value for the sedimentation rate of bushy stunt virus has recently been confirmed by Ogston [*Biochem. J.*, 37, 78 (1943)], who stated that McFarlane and Kekwick regard the higher value they obtained in their initial study as being in error due probably to unsuspected irregularities in temperature in the rotor.

The discrepancy between this value and the 7.4×10^6 obtained from sedimentation data alone could possibly mean that the assumption that the particles are unhydrated spheres is not valid. Had it been assumed either that the virus particles are hydrated spheres containing about 67 per cent water on a dry basis or that they are unhydrated rods or disks with asymmetries of 5:1, the value calculated from sedimentation data alone would have been in agreement with this value of 10.6×10^6 . It is not possible, however, to rationalize this value with that obtained from sedimentation equilibrium without questioning the accuracy of one or the other.

FIGURE 17. Theoretical vs. actual boundary spreading in sedimentation experiment on bushy stunt virus. Open circles are experimental points obtained by Lamm Scale method. Smooth curves are theoretical boundaries calculated from known diffusion constant. The times in minutes and scale cell distances in centimeters for the successive boundary curves, beginning at the left, are: 50, 2.1; 85, 3.1; 135, 4.1; 150, 4.6; 220, 5.6. (From Lauffer.⁴⁵)

The fact that the distribution of bushy stunt virus particles in sedimentation equilibrium studies is approximately of the theoretical form indicates that the virus solutions are reasonably homogeneous. A much more sensitive criterion of homogeneity may be afforded by sedimentation velocity experiments. In every such experiment, the sedimenting boundary becomes progressively more diffuse. This may be caused entirely by diffusion, or by diffusion and inhomogeneity. The spreading of a sedimenting bushy stunt virus boundary was measured very carefully by the Lamm Scale method.⁴⁵ Then the theoretical boundary spreading was calculated from the diffusion constant, on the assumption that the virus particles are all of the same size and shape. The results are illustrated in Fig. 17, where the open circles are the experimental data and the smooth curves the theoretical boundaries. The diffusion constant was taken to be 1.15×10^{-7} . The excellent agreement demonstrates that the observed boundary spreading can be accounted for completely by the known diffusion rate of the virus. This fact is entirely consistent with the supposition that the virus is absolutely homogeneous and that the virus particles are therefore molecules. The data demonstrate conclusively that, if the particles are not homogeneous, the standard deviation of the distribution of particle diameters must be less than 1 per cent of the mean diameter.

Electrophoresis experiments conducted by McFarlane and Kekwick⁶² indicate that the virus is homogeneous with respect to electrochemical behavior. This evidence is also consistent with the idea that the virus particles are molecular in nature. The isoelectric point of the material was found to be at pH 4.2 and the

electrophoretic mobility was found to change 0.4μ per second per pH unit in unit field.

The x-ray diffraction pattern of crystals of bushy stunt virus suspended in their mother liquid was studied by the powder method by Bernal, Fankuchen, and Riley.^{11, 12} They observed two lines which correspond to spacings of 279 Å and 160 Å, respectively. The relationship between them is expressed by the ratio 3:1. Because the crystals are dodecahedra, the investigators assumed that the crystal lattice is body-centered, and they ascribed these two spacings to 110 and 112 planes. From this it can be computed that the edge of a unit cell would be 394 Å. The density of the wet crystals was taken to be 1.286. However, such a high value is not compatible with the known density of the virus particles and the amount of hydration indicated for the wet crystals. A value for the density, calculated from theory, of 1.18 would seem to be a much more reasonable figure. Since there are two molecules in a body-centered unit cell, one can calculate a value of 22×10^6 for the wet molecular weight of bushy stunt virus. Had the investigators assumed that the observed spacings corresponded to 100 and 111 planes of a simple cubic lattice, they would have calculated a unit cell of 279 Å on edge containing only one molecule. This would give a wet molecular weight of 15.6×10^6 . These workers also observed that, as crystals of bushy stunt virus are dried, they shrink symmetrically to final dimensions about 80 per cent of those in the wet state. This shrinkage is paralleled by a corresponding decrease of the same magnitude in the crystal lattice. From this fact it can be calculated that a wet crystal of the virus contains 0.67 gram of water for each gram of dry protein. Hence, the dry molecular weight of the virus would be 9.35×10^6 or 13.2×10^6 , depending upon whether the crystal lattice is assumed to be simple cubic or face-centered. The lower of these is somewhat too high to agree with the value of the molecular weight calculated from centrifugation studies alone, 7.5×10^6 , and the higher is too high to agree with that calculated from a combination of sedimentation and diffusion data. This discrepancy can be met by assuming that a perfectly dry virus crystal can soak up about 15 per cent of its own volume of water before the crystal begins to swell, that is, that it can hold 15 per cent by volume of water zeolytically. On this assumption, the dry molecular weight calculated for a simple cubic cell would be 7.9×10^6 , and that calculated for a face-centered lattice would be 11.2×10^6 .

Electron micrographs of bushy stunt virus have been obtained.¹⁰¹ The particles appear to be essentially spherical in shape, with a diameter of about 26 μ . This value is in excellent agreement with that calculated from sedimentation velocity data on the assumption that the particles are unhydrated spheres. The filtration end point of this virus was found to be 40 μ , indicating that the particles are 13-20 μ in diameter.⁸⁹ Hence, these data also agree in general with the other studies on the size of the bushy stunt particle.

Diffusion, sedimentation velocity, sedimentation equilibrium, and electrophoresis experiments all indicate that bushy stunt virus nucleoprotein preparations possess a degree of physical homogeneity heretofore never demonstrated for any virus protein. The physical evidence for absolute homogeneity, which is demanded of the particles if they are to be regarded as molecules in the strictest sense, is as good as that for any of the proteins generally conceded to be in a molecular state. There is still an unresolved discrepancy in the data relative to the molecular weight of the virus, but the evidence indicates that the particles are unhydrated spheres with a molecular weight of about $7\frac{1}{2}$ million, or either hydrated spheres or non-spherical bodies with a molecular weight of about $10\frac{1}{2}$ million.

The colloid-chemical properties, particularly the size and shape, of two viruses have been considered in detail. Although few other viruses have been studied to the same extent as these two, considerable evidence is available defining at least the order of magnitude of the sizes of many other viruses. This evidence is sum-

COMPARATIVE SIZES OF VIRUSES

| | Molecular weight X 10 ⁻⁶ (Particle weight x 6.06 x 10 ¹⁷) | Diam or length X width in mμ | |

The Gene—A Structure of Colloidal Dimensions

JEROME ALEXANDER

Genetics is a branch of biology dealing with heredity and its variations, and the mechanisms underlying these phenomena. The following historical summary and glossary have been prepared for the benefit of those users of this series who have not kept in touch with the fascinating developments in genetics, leading to demonstration of the fact that genes are specific structures of colloidal dimensions. The paper by J. Alexander and C. B. Bridges in Vol. II of this series, entitled "Some Physico-chemical Aspects of Life, Mutation and Evolution," gives considerable genetic data, including (p. 36) a diagrammatic sketch of the chromosome cycle in cell division. The following is largely based on an outline in "Colloid Chemistry," by J. Alexander* from which most of the illustrations included here have been reproduced.

In 1865 Gregor Mendel, Abbott of Brunn (Bohemia), published results of the breeding experiments he had carried out in his cloister garden with the common pea (*Pisum sativum*); but it was not until 1900, eighteen years after his death, that the importance of his work was recognized by three distinguished botanists, Hugo de Vries, C. Correns, and E. Tschermak. Mendel crossed a tall with a dwarf pea, and focussed his attention on how these characteristics were inherited. All members of the first hybrid family (F_1) were tall.

Mendel's First Law: Segregation. The second family (F_2) developing from the seeds of the F_1 hybrids, always gave an average ratio of three tall to one dwarf. The F_2 dwarfs always bred true to type, as did also one-third of the tall. The other two-thirds of the tall behaved like the original F_1 hybrids, i.e., they gave in F_3 three

* 4th edition, D. Van Nostrand Co. N. Y., 1937.

talls to one dwarf. Mendel termed "tallness" a *dominant* character and "dwarfness" a *recessive* character because it reappeared in subsequent generations raised from the hybrid type seed. He also obtained similar results with several other pairs of contrasting character. The following diagram illustrates the results, R indicating plants with a recessive character, D dominants which breed true, and D dominants which carry the recessive type:

Mendel pointed out that this segregation of characters in a 3 to 1 ratio could be explained by assuming that they were determined by discrete representative producers (later called genes). Though each cell of the hybrids F_1 would develop under the joint control of a dominant and a recessive gene, in both ova and pollen these factors separate cleanly from each other (segregate), so that, according to the laws of chance, each ovum or pollen grain would get a pure dominant gene, D , or equally often a pure recessive gene, R . Thus with random or haphazard fertilizations, we would get

leading to an F_2 family $D/D; (D/R, D/R); R/R$.

As a test for this hypothesis, Mendel fertilized *dwarf* flowers with pollen from F_1 hybrids, obtaining, as he had expected, *equal* numbers of tall- and dwarf-producing seeds, as the following diagram indicates:

Mendel's Second Law: Independent Assortment. On crossing peas having *yellow and round* seeds with peas having *green and wrinkled* seeds, Mendel found that the F_1 seeds were all yellow and round, these characters being dominant over the recessive alternates green and wrinkled. The plants from these F_1 seeds, when self-fertilized, yielded seeds (and therefore progeny) of four types: yellow-round; yellow-wrinkled; green-round; green-wrinkled, in the ratios 9:3:3:1. Mendel explained these results by assuming that the distribution of the segregated genes of the pair green/yellow takes place independently of the round/wrinkled segregated pair. That is, there would be four equally numerous kinds of ova and four equally numerous kinds of pollen grains, which, uniting at random during fertilization, would give sixteen different combinations in the 9:3:3:1 ratio found in the visible types.

Linkage. This is a failure of random assortment, understandable on the assumption that the genes of the two pairs which fail to assort at random act as discrete units (gene blocks) in the chromosomes, microscopically resolvable bodies containing invisible genes arranged in linear order. Just after the resurrection of Mendel's work, the phenomenon of linkage was observed by Sir William Bateson and R. C. Punnett * in experiments with sweet peas, in which they found that the factor pairs

* Second Rept., Evolution Committee, Royal Soc., London, 1905.

(red vs. purple flower) and (long vs. round pollen grain) did *not* assort at random. When (red) and (long) entered a cross together, they tended to remain together in subsequent generations to a greater extent than expected under random assortment.

FIGURE 1.

Variations in Chromosomal Behavior. *Crossing-over*, the commonest of these, is illustrated in Fig. 1, and occurs when two chromosomes of a pair twist about each other in some stage of germ cell formation (meiosis). Less common are: *inversion*, which occurs when a block of genes breaks loose from a chromosome and returns to that chromosome "upside down"; *translocation*, which occurs when the loose gene-block joins another chromosome; *deletion* or *deficiency*, which occurs if the loose gene-block is lost. These phenomena are diagrammed in Fig. 2.

FIGURE 2.

***Drosophila melanogaster*.** This tiny yeast-eating "fruit fly" has been largely used by T. H. Morgan (Nobel Laureate, 1935) and his school, as well as by many others, in speeding up genetic experiments. The fly matures in about 10 days and

lives about 30 days. About thirty or more prolific generations can be cheaply raised in a year, in glass bottles in the laboratory, independent of weather conditions. The breeding and crossing of strains is readily controlled, and there are many easily recognizable variations. A "gene map" prepared by C. B. Bridges is shown in Fig. 3,

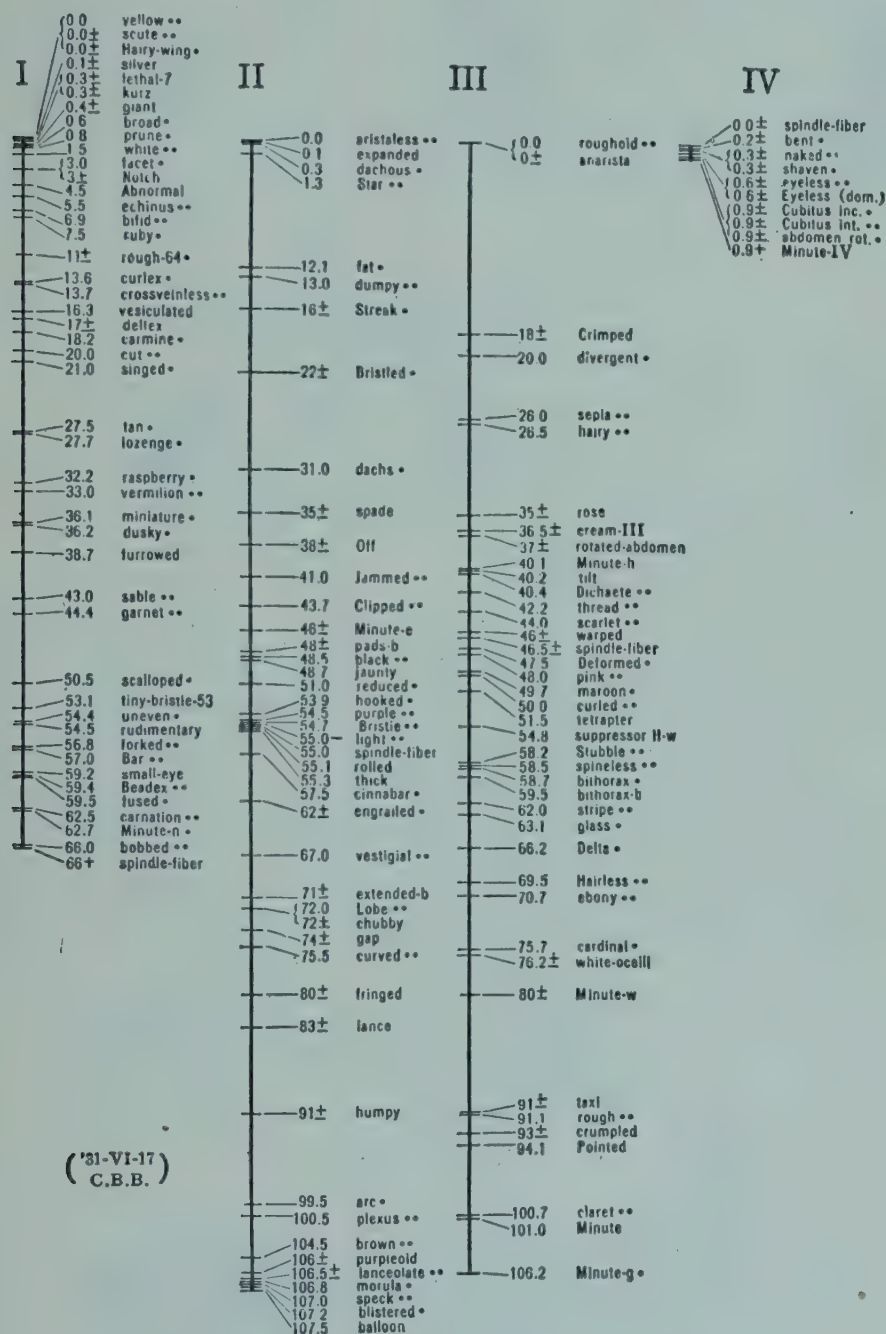

FIGURE 3. Genic map of the four chromosomes of *Drosophila melanogaster*, showing the linear order and distance apart of the genes (after Calvin B. Bridges).

which shows the relative positions of numerous genes dominating the characteristics indicated in the "shorthand" of geneticists. Some of these characters, e.g., vestigial wing, are most striking, and are illustrated in Fig. 4. A large variety of plants and animals are used in genetic experiments, including microorganisms.

FIGURE 4. A—Normal wild-type female *Drosophila*, gray body color, red eyes, long wings, absence of speck at base of wings.
 B—Male *Drosophila* having four linked, recessive characters, viz., black body color, purple eyes, vestigial wings, and speck at the base of the wings.
 C—Fly showing the mutant character "Curly." (The wings curl up at the ends and are held somewhat apart.)
 D—Eye of female fly homozygous for "Bar" (eye is bar-shaped).
 E—Fly showing the mutant character "Lobe²". (The eyes are small and protruding.)

These illustrations are reproduced from "The Theory of the Gene" by Thomas Hunt Morgan, Nobel Laureate. (Yale Univ. Press, 1926)

FIGURE 5. Salivary gland chromosome from *Drosophila melanogaster*.

An outstanding advance was made in 1927 by H. J. Muller, who demonstrated the "artificial transmutation of the gene" by x-rays* and this work has been greatly extended. Another great advance was due to the observation (1935) by T. S. Painter that the cells in the salivary gland of the tiny fruit fly grub have chromosomes which are from 175 to 200 times the size of ordinary chromosomes, and which, on staining, reveal a "genetic spectrum," a series of characteristic bands varying with and corre-

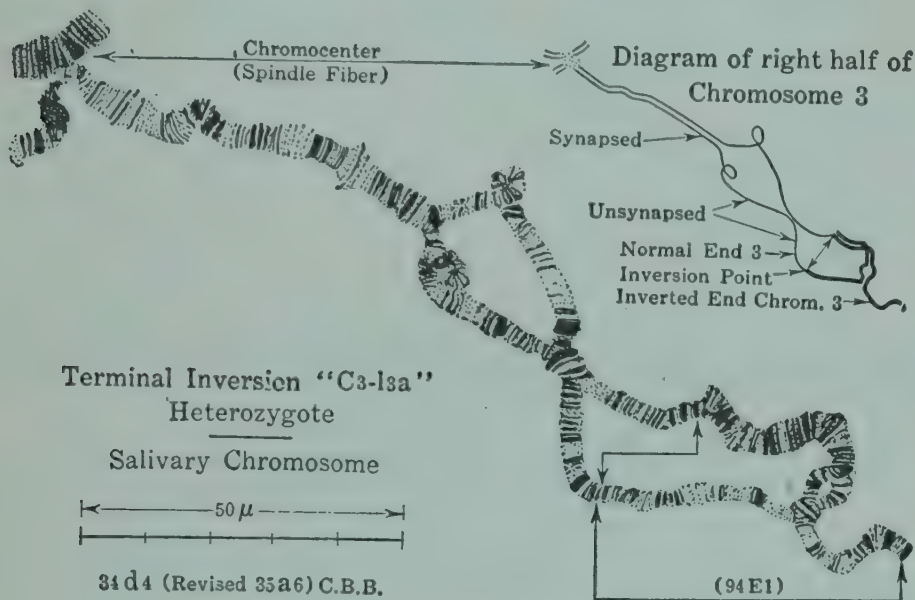

FIGURE 6.

sponding to the genetic constitution of the animal. The upper right-hand corner of Fig. 5 (scale of magnification indicated) shows the four *Drosophila* chromosomes as usually observed, the arrow indicating the two tiny chromosomes which, in the main part of the cut, are shown as they appear in the salivary glands, under the same magnification. In Fig. 6 we have a case of a salivary gland chromosome where com-

FIGURE 7.

plete synapsis has failed because of a terminal inversion. Fig. 7 shows a deficiency in a salivary-gland chromosome, lack of the gene-block causing an outward looping of the normal chromosome during conjugation. In Fig. 8 we have a portion of a salivary-gland chromosome, showing how the gene map finds its visual check in the

* *Science*, 66, 84-87 (1927).

"genetic spectrum." More complete concordances are illustrated in the elaborate chromosome maps published in the *Journal of Heredity* (1935 *et seq.*).

FIGURE 8. Section of the right end of second chromosome (salivary gland of *Drosophila melanogaster*) with corresponding portion of the chromosome map (after Calvin B. Bridges).

Sex Determination. Chromosomes of a predominant type are called *autosomes*, in contradistinction to the one or more pairs of "sex chromosomes" whose segregation determines the sex of each offspring. The basic sex chromosome, known as the X-chromosome, has no discovered mate in some species (XX-XO) types, while in other species it has a mate, the Y-chromosome (XX-XY types). Comparatively recently, the Y-chromosome was found in human sperm, placing man in a major XX-XY group in which the fertilized ovum that develops into a female has two X-chromosomes, whereas the male has one X and usually one Y. In man, reduction-division leaves the female gamete (ovum) with one X-chromosome, while the sperms are equally divided between X and Y, the sex of the human being determined by which kind of sperm chances to fertilize the ovum. In another group, including birds and moths, it is the female that has differencing sex chromosomes (WZ), male cells being (ZZ) and yielding only Z sperms. The following diagrams indicate how these microscopic gene-carrying units dominate sex-determination:

The 48 chromosomes of man, 24 from each parent, are outlined in Fig. 9. In sex as in all other cellular developments, *all* the genes exert an influence, the net emergent results (only some of which may be easily demonstrable) depending upon the final results of the complex cellular catalyses, a summation expressed in the term *genetic balance*. The biont (plant or animal) may die or may fail to reproduce if genic ba

ance is too greatly disturbed. Thus when the chromosome pairs fail to separate in reduction-division (a phenomenon termed *non-disjunction*), abnormal numbers of chromosomes may enter a germ cell and thus enter the zygote. Some of the consequences with *Drosophila* are tabulated below, A representing a single set of autosomes; each parent contributes one autosome set.

| Chromosomal Constitution | Sex of Individual |
|---------------------------|---------------------------------|
| AAXY (normal diploid fly) | Male (normal) |
| AAXX " " " | Female (normal) |
| AAXXY | Female, giving abnormalities |
| AAXXX | "Superfemale," abnormal |
| AAXO | Male, sterile |
| AAYO | Dies,-sex? |
| AAAXXX (triploid fly) | Female, producing abnormalities |
| AAAXX | Intersex, sterile |
| AAAXXY | " " |
| AAAXY | "Super-male," sterile |

In tracing demonstrable changes occurring in biological and technological phenomena, chemists naturally try to identify definite chemical compounds in every stage of each process; and this is often possible. But as has been pointed out repeatedly in this series, *e.g.*, on p. 11 of Vol. II, in a paper by J. Alexander and

FIGURE 9. The 48 human chromosomes, in outline (after H. M. Evans and O. Swezy, Mem. Univ. Cal., Vol. 9, No. 1, 1929).

C. B. Bridges, the line of demarcation between "chemical compounds" and "physical combinations" is purely a matter of convention and convenience. Nature is oblivious of textbook definitions. In his book on "The Nature of the Chemical Bond" (Cornell Univ. Press, 1939) Linus Pauling defines the chemical bond as follows (p. 3):

"We shall say that there is a chemical bond between two atoms or groups of atoms in case that the forces acting between them are such as to lead to the formation of an aggregate with sufficient stability to make it convenient for the chemist to consider it as an independent molecular species."

Where biological or technological "aggregates" lack the definiteness and stability entitling them to be called "chemical compounds," we must not close our eyes to the fact that they actually *are* aggregates, and that their existence, even though transitory, may be of great importance in the explanation and the outcome of a process.

It is hoped that the above brief outline will lead the reader to seek specialized books on genetics for further information. Before appending a brief glossary, we add the following quotation from a chapter on "The Genetics of Sex in *Drosophila*," by C. B. Bridges in "Sex and Internal Secretions," edited by Dr. Edgar Allen:

"Considered from the standpoint of its products, each gene is a chemical factory, devoted to the manufacture of a series of active chemicals and their delivery in sequence to the surrounding chromosomoplasm. Each gene in a given gene-string or chromosome has its own 'orders' to fill, and has the machinery for producing its particular set of manufactured chemicals. A chromosome is like a row of factories set upon the bank of a canal, all delivering their goods by means of the waters of the canal, as well as helping themselves to raw material brought by the canal."

Glossary of Some Terms Used by Geneticists *

- Allclomorph** (Allel, or Allele): The alternative form of a gene, having the same locus in homologous chromosomes. Thus in many organisms there is a gene which produces albinism. This is usually recessive to the gene for normal pigmentation, which is a dominant allelomorph of albinism.
- Anaphase**: The later stages of mitosis during which the daughter chromosomes diverge from the equatorial plate.
- Atavism**: Reappearance of a character after a lapse of one or more generations, as when a recessive character reappears after having been transmitted through several generations of heterozygous individuals.
- Backcross**: The mating of an F_1 hybrid to one of the parental races crossed to produce this hybrid.
- Blastomere**: One of the cluster of cells formed as a result of the first few divisions of the animal egg.
- Centrosome**: A minute body generally present in animal cells and in the cells of some lower plants, but rarely visible in flowering plants. It is the center of the *astral rays* (which appear during mitosis, and form the *aster*) which play an important part in cell division.
- Character** (short for "characteristic"): A term used, often rather vaguely, to designate any form, function, or feature of an organism. The Mendelian characters of genetics represent the end products of development in which a definite gene, or genes, has a decisive effect. "The constant and unchanging thing, therefore, is the factor (gene) itself rather than the character, and the unity which Mendel observed lies rather in this underlying factor than in the visible, and perhaps variable character which it produces." (Sinnott and Dunn).
- Chiasma**: "In the diplotene stage (in meiosis, this precedes diakinesis) the chromatids are associated in pairs in such a way that in one part of their length chromatids are associated but in another part each is associated with a different chromatid. The point of exchange is termed a chiasma." (Sansome and Phipp, 1932).
- Chromatid**: Chromosomes frequently bear the foreshadowing of one or more longitudinal divisions so that they appear to be made up of parallel threads. These threads are the chromatids.
- Chromatin**: That part of the nuclear substance which forms the most conspicuous part of the nuclear network and the chromosomes, and stains deeply with "nuclear" or basic dyes.
- Chromocenter**: Inert chromatin to which the chromosome elements are attached in the salivary glands of the *Diptera*.
- Chromomere**: One of the linearly arranged chromatin granules comprising the chromosome. (Identified by Belling and others with the gene, but by more recent workers considered an artifact produced by fixation of spirally coiled chromatids.)
- Chromonema**: A fine thread of chromatin material from which arises the spireme thread.
- Chromosome Map**: A diagram showing the relative positions of genes in linkage groups, determined by observation of cross-over frequencies, or by other means.
- Chromosomes**: Tiny, dark-staining bodies visible under the microscope in the nucleus of the cell at the time of cell-division. The number of chromosomes in any species is usually constant. The chromosomes carry the genes, linearly arranged.
- Conjugation**: Side-by-side association of homologous chromosomes as in the reduction division.
- Crossing Over**: The exchange of linkage relations between two characters due to an interchange of segments between the chromatids of two homologous chromosomes in the germ cells early in meiosis. This results in a change in the linkage relations of the characters as they appeared in the parents. See *Chiasma*.
- Cytoplasm**: The protoplasm of a cell in which the cell organs (nucleus, plastids) are embedded.
- Cytoplasmic**: Pertaining to the protoplasm outside of the nucleus; said of inheritance dependent on the cytoplasm or on objects contained in it.
- Diakinesis**: A stage of meiosis in which the homologous chromosomes are associated in pairs, just before reduction, when the pairs separate to complete the heterotypic mitosis in which the chromosome number is reduced.
- Differentiation**: The process whereby cells and tissues become specialized for specific functions during the process of growth and development.

* Based mainly on "A Glossary of Genetic Terms," published in the *Journal of Heredity*, 28, pp. 71-80 (1937), assembled over twenty years "to make understandable to the not over-technical reader the peculiar lingo of genetics." Words understandable from the text of this book are for the most part omitted.

- Diploid:** Having two sets of chromosomes. Body-tissues of higher plants and animals are ordinarily diploid in chromosome constitution, in contrast with the haploid gametes. See *Somatic*.
- Epigenesis:** The concept of generation now accepted by biologists, which holds that the germ or embryo develops afresh in each generation through the interaction of genes and other protoplasmic components with the environment, in contrast with the theory once held that development was merely an unfolding of organs already microscopically present in the egg.
- Epistasis:** The suppression of the action of a gene or pair of genes not allelomorphous to the gene suppressed. Thus, the gene for wild pattern (agouti) in the rabbit is masked in the albino. Albinism in this case is said to be epistatic over the wild pattern, which is hypostatic to albinism.
- Equatorial Plate:** The figure formed by the metaphase chromosomes lying in the equator of the spindle during mitosis.
- Eugenics:** The application of knowledge of heredity to the improvement of the human race. "The study of agencies under social control that may improve or impair the racial qualities of future generations, either physically or mentally."
- Fertilization:** The name given to the events occurring after pollination or mating, which culminate in the fusion of a male gamete with an egg (ovum) and initiate the development of an embryo.
- Gamete:** A reproductive cell of either sex; e.g., a sperm or an egg (ovum).
- Gene:** (1) The unit of inheritance, which is transmitted in the germ cells, and which, by interaction with the genic and cytoplasmic complex and the environment, controls the development of a character. The alternative units (allelomorphs), occupying the same locus in a chromosome, are held to be phases of the same gene. The genes are held to be linearly arranged in the chromosomes. (2) "The physical basis of heredity."
- Genom:** A chromosome set, as it is inherited as a unit from one parent.
- Genotype:** The entire genetic constitution, expressed and latent, of an organism, in contrast to *phenotype*.
- Germ Plasm:** The material basis of heredity, taken collectively. The sum of the gene-constitution of an organism.
- Gynandromorph:** An individual of which one part of the body is female in constitution, and another part is male.
- Haploid:** Single; referring to the reduced number of chromosomes, as in the mature germ cells of bisexual organisms. Cf. *diploid*.
- Heterotypic division:** One of the two meiotic divisions, in which the homologous chromosomes are separated to form daughter cells with the haploid chromosome number.
- Heterozygote:** An organism heterozygous (hybrid) with respect to any given pair of allelomorphs; that is, containing two different forms of the same gene.
- Homeosynapsis:** Synapsis between like chromosomes.
- Homologous:** Chromosomes occur in somatic cells in pairs; two members of a pair are spoken of as homologous chromosomes.
- Homozygous:** (1) (An organism) formed by germ cells alike with respect to a given gene. (2) An organism is said to be homozygous for a given character when all the germ cells transmit identical genes for that character. This is the most frequently used meaning of the term.
- Identical twins:** Two individuals developed from the same fertilized egg. They are extremely alike and are generally (but not always) found in the same chorion before birth. Monozygotic twins.
- Interchange:** An exchange of segments of non-homologous chromosomes.
- Intersex:** An organism displaying sexual characters and secondary sexual characters intermediate between male and female.
- Leptotene:** A term applied to the fine spireme-thread stage of the chromosomes before their union in synapsis.
- Linkage:** Association of characters in inheritance, due to the fact that the genes determining them are physically located in the same chromosome. Such a group of linked characters is termed a linkage group.
- Locus:** The position occupied by a gene on a chromosome, in a linkage group, or on a chromosome map.
- Maturation Divisions:** Meiosis.
- Meiosis:** The two divisions which precede the formation of gametes (or in plants the development of a gametophyte), in which the members of each chromosome pair separate, and the chromosome number in the resulting daughter cells is reduced to half the somatic number, as distinguished from ordinary cell division (mitosis).
- Metaphase:** That stage in cell division in which the chromosomes are arranged in an equatorial plate.

- Mitosis:** Cell division involving the formation (by self-duplication) of chromosomes, of spindle fibers, and the division of the chromosomes by a process of longitudinal splitting. Thus each daughter cell gets a full complement of the chromosomes which existed in the original cell before division. [Since the division of the cytoplasm between the daughter cells is not so precise, inequalities may occur in the distribution of the cytoplasm and any of its small randomly dispersed units].
- Modifier or Modifying Gene:** A gene which affects the expression of another gene.
- Monoploid, Haploid:** Also sometimes used in the sense of the basic haploid chromosome number in a ploid series. Thus in the genus *Rosa*, species are known in which the haploid chromosome numbers are 7, 14, 21, or 28 (the respective somatic chromosome numbers being 14, 28, 42 and 56). In this polyploid series the monoploid ("basic haploid") chromosome number is 7, but the haploid number in any given species of the series may be 7, 14, 21, etc., depending on whether the form is diploid, triploid, etc., in terms of the seven fundamental monoploid chromosomes.
- Mosaic:** An organism, part of which is made up of tissue genetically different from the remaining part. Mosaics are produced by mutations during development, or by chromosome non-disjunction, or by double fertilization of an egg, or in other ways.
- Mutation:** A sudden variation which is inherited, resulting in changes in the gene or genes concerned. The term is used rather indefinitely, to include "point mutations" (of a single gene) and chromosome deletions, rearrangements, duplications, chimeral changes, de Vriesian mutations, etc.
- Mutual Translocation:** Reciprocal transfer of parts of two non-homologous chromosomes. "Essentially crossing-over between non-homologous chromosomes."
- Non-disjunction:** (1) Failure of chromosome halves to separate in cell division, both halves going to the same daughter cell. (2) Failure of a pair of synapsed chromosomes to separate at the reduction division, both chromosomes of the pair going to the same gamete.
- Nucleolus:** A darkly staining body found in the nuclei of most cells. Its function is not clearly understood.
- Nucleus:** A highly refractive, deeply staining body of specialized protoplasm found within the cells of all organisms except bacteria. It contains the chromosomes and the karyolymph, the nucleolus, etc.
- Ontogeny:** The developmental history of an organism from egg (spore, bud, etc.) to adult individual.
- Oöcyte:** A female reproductive cell during oögenesis, up to the time of the second division. Oöcytes are designated as *primary* before the completion of the first division, then *secondary* thereafter. *Primary* have the diploid chromosome number and *secondary* the haploid chromosome number.
- Pangen:** A hypothetical particle (which might be likened to a "floating gene") suggested by Darwin as an explanation of inheritance and modification of characters in his pangenesis hypothesis.
- Parthenogenesis:** The development of a new individual from a female germ cell without fertilization.
- Phenotype:** The organism as exemplified by its expressed characters, as contrasted with its genetic constitution (the genotype).
- Phylogeny:** The evolutionary history of a species, genus, or type.
- Plastid:** One of the several kinds of protoplasmic bodies in cells, like the chlorophyll bodies in plant cells, which are centers of chemical activity.
- Plastid Inheritance:** Inheritance through plastids carried in the cytoplasm of the ovum. Variegation in several plants is known to be inherited in this manner.
- Polar Body:** A minute cell of which two are cast off and discarded from the animal ovum during maturation.
- Prophase:** The stage in cell division prior to the metaphase, during which the chromosomes appear in the nucleus, following the resting stage.
- Protoplasm:** "The physical basis of life"; a chemical compound or probably an emulsion of numerous compounds. It contains proteins which differ slightly in each species of organism. It contains carbon, hydrogen, oxygen, nitrogen and various salts, but is so complex as to defy structural analysis. [In a paper entitled "Some Chemical Aspects of Life, Food and Evolution" published in *Scientia* (Milan), Oct. 1933, J. Alexander stated: "Although isolated protoplasm may maintain activity for a short time under suitable conditions, it is incapable of self-reproduction and should be regarded rather as a highly specific milieu in which the real living self-reproductive units of cells exist and function. The concept of protoplasm as the ultimate 'living jelly' is a relic of antiquated text-books and should be definitely abandoned. The modern concept of protoplasm embraces the cytoplasm *with* its included nuclear and other particulate units." J. A.]

- Reciprocal*: Involving the same types of individuals, but with the sexes reversed; said of two crosses, in one of which the female possesses the same character as does the male in the other cross, and *vice versa*.
- Recombination*: An offspring which has a combination of linked characters different from that exhibited by the parents.
- Reduction Division*: The heterotypic division (*q.v.*).
- Sex-Limited*: Expression of a character in only one sex. Examples: milk production; horns in Rambouillet sheep; egg production.
- Sibling (Sib)*: One of two or more children of the same parents, but not of the same birth.
- Somatic*: Referring to body tissues; having two sets of chromosomes, one set coming normally from the female parent and one from the male; as contrasted with mature germ cells having a single set of chromosomes.
- Somatic Mutation*: A mutation in a somatic cell, resulting in a chimera individual with respect to the mutant character.
- Spermatid*: One of the two cells formed by the second division in spermatogenesis. By transformation in shape the spermatids become mature spermatozoa.
- Spindle*: A group of structures, observed in fixed cytological preparations, resembling threads, in the form of a spindle, formed during mitosis.
- Sport*: An abrupt deviation from type. An obsolescent term for mutation.
- Synapsis*: The conjugation or union in pairs of homologous chromosomes, respectively of maternal and paternal origin, to form bivalents; the primary step in meiosis.
- Telophase*: The closing phase of mitosis, during which the daughter nuclei are formed and the mother cell usually divides.
- Test Cross*: A backcross of a diheterozygote to a double recessive, to test linkage.
- Tetraploid*: An organism whose cells contain four haploid (monoploid) sets of chromosomes.
- Trait*: A term loosely used by geneticists as a synonym for "character."
- Translocation*: Attachment of a fragment of one chromosome to a non-homologous chromosome, resulting in a new arrangement of genes.
- Triploid*: An organism characterized by having three times the haploid (or monoploid) chromosome number.
- Unit Character*: A heredity trait that behaves as a unit in transmission, being capable of inheritance independently of other unit characters and determined by the allelomorphs of a single gene. Example: green and yellow seed color in peas.
- Variation*: In biology, the occurrence of differences among individuals of the same species.
- Variety*: In taxonomy, a division of a species; a group of individuals within a species which differ in some minor respect from the rest of the species. Agronomic varieties are the product of human selection, and differ in characters of economic importance.
- Xenoplastic Graft*: A heteroplastic graft that "takes" and continues to develop in its new site (most heteroplastic grafts are short-lived).
- Zygote*: The cell produced by the union of two cells (gametes) in reproduction; also the individual developing from such a combined cell.
- Zygotene*: A stage in meiosis, preceding synapsis (also called synezeis), during which the chromosome homologs begin to pair.

The Gene as a Chemical Unit

JACK SCHULTZ

The Lankenau Hospital Research Institute, Philadelphia, Pa.

The Genetic Technique and the Definition of the Gene

It is now a commonplace of biological thinking that the basic units of the living world are the genes. The experiments upon which this view is based owe their success to a special technique, peculiar to the field. This technique consists in the utilization of the internal variations of the biological system as indicators of the behavior of special components of that system. Mendel defined the individual units which we now call the genes in terms of their variants. And these inferred variants

of the ultimate units were recognized by the directly observable differences in the organism. Traced to their origins, these must in turn be the consequence of differences in the developmental processes of the standard type and its variant. For the definition of the gene as a hereditary unit, however, it was sufficient that the behavior of the hereditary system was explicable in terms of the interaction of these units. The nature of the changes in the postulated units, and how the observed differences could be traced to these changes, could be ignored. The result was the definition of the gene as a structural unit in the cell; and this definition was amply justified by the visible identification of these structural units as the elements composing the chromosomes.

With the increase of knowledge, a definition of the gene has evolved based upon its function in development. The early views of the nature of the gene, considering it essentially to be the archetype of intracellular catalyst, were founded on an argument by analogy. Minute in quantity compared to its effects and (so the argument went) not itself changed by the reaction it facilitated, the hereditary unit was compared to an enzyme (Troland 1917, Muller 1923, 1929, Alexander and Bridges 1928; see the review by Wright 1941); but an enzyme of a peculiar and unique type, an autocatalyst, which in addition to catalyzing other reactions, itself was the progenitor of its own kind (cf. Morgan 1926).^{*} It is evident that the establishment of a comparison of this kind requires experiments in the domain which had been disregarded in the primary analysis of the hereditary mechanism. Now the nature of the developmental change must be studied, and the attempt to define a gene in terms of its function leads us into chemical embryology. A change in the sequence of developmental reactions is effected by the substitution of a mutant gene for the normal one; thus a specific series of synthetic reactions is dissociated from the welter going on in development. The precise determination of the differential reactions can then guide us towards a functional definition of the gene. As a result of many analyses of this kind, the picture has emerged of a network of reactions occurring in development (for references see Goldschmidt 1939, Wright 1941, Haldane 1942, and the chapters on physiological aspects of genetics in the Annual Reviews of Physiology). Each of these reactions is presumed to be governed by its specific catalyst; and in some cases it has been demonstrated that the synthesis of the catalyst itself is changed in the mutant type (Daneel 1941, Moewus 1941). Thus the early analogy with enzymatic processes is correct in principle: functionally the gene is concerned with the production of the enzymes of biosynthesis.

But for the precise definition of the gene as a chemical unit evidence of still another sort is required. The enzymes of biosynthesis must be traced to their source in the chromosomes. And the direct analysis of the chromosomes themselves provides the starting point here. The substances of the chromosomes must include the genes and possibly their primary products. Hence the development of techniques whereby the transformations of these substances can be followed within the cell, makes possible the critical experiments. These have as their aim the pursuit of synthesis in the individual cell from the initial reaction in the chromosome to the final effects in the cytoplasm. Analyses of this kind have only begun; they are essential in that they provide the topographical evidence needed to complete a functional definition of the gene.

From the point of view of biochemistry, it is evident that the genetic technique, with the implied analysis of the gene as a chemical unit, is basically an attempt at the study of synthetic processes in the intact organism. The degree to which these attempts are successful is reflected in the accuracy and the detail of the definition of the gene. In the following, we shall consider the genetic evidence for the existence of genes as separable units, more or less autonomous in function. It will be seen that

^{*} Several papers in this volume deal with heritable changes in biocatalysts, as well as with *catalyst modification*, a notion advanced by J. Alexander (*Protoplasma*, 1931).

this involves consideration of their arrangement in the chromosomes, of the mechanism of the maintenance of this arrangement, of questions of gene change and the like. Having discussed these problems, we will proceed to the discussion of the chemical evidence associating special constituents of the chromosomes with genic activity. It will appear in the sequel that the evidence is accumulating for the concept that the genes are nucleoprotein in nature, and that their primary functional activities are concerned with a system of nucleoprotein syntheses which lie at the basis of the synthetic activities of the cell.

The Linear Order of the Genes

The first experimental demonstration that the specific hereditary units are arranged in linear order in the chromosomes came from the study of the phenomenon called crossing over (Morgan 1911, Sturtevant 1913). It is the separation from each other of linked characters in breeding experiments that is crucial. For one of the major criteria for the distinction between the several genes within a chromosome is the production, by hybrids for a number of variants, of gametes containing recombinations of the original characters. In other words, the individual units are separated by a process of exchange between the chromosomes. How far these units are the irreducible elements will be discussed presently. But it is the circumstance that this particular system of producing new combinations happens to be prevalent among animals and plants, that is at the basis of the elaboration of Mendelian heredity into the theory of the gene. There is no need here to review the experiments that have been carried out: their major result, the construction of the classical chromosome maps of *Drosophila*, is sufficiently well known (for an introductory account, see the text of Sturtevant and Beadle 1939).* It is one of the familiar triumphs of genetic and cytological analysis that the correspondence is complete between the linear sequence deduced from the breeding experiments and that observed in the microscopic analysis of the chromosomes themselves (Painter 1934, Bridges 1935).

The linear order of the elements of the chromosomes was first inferred from the fact of the division of the chromosomes, as a necessity if mitosis were to be equal. The same line of reasoning is in fact now used to argue for the necessity of a two dimensional arrangement to permit the synthesis of identical molecules. It is not so frequently realized that there are further implications of the argument. An arrangement in a linear series is also convenient for the maintenance of precise relations for functional purposes, assuming for example that the individual members are centers of synthesis. But does the linear series persist during the functional phases of the nucleus?

The synthetic work of the nucleus is performed during the interphases, when the chromosomes have undergone a series of maneuvers whose end is the formation of a functional nucleus. Within this, the unwound spirals of the metaphase chromosomes persist, with their nucleolar products; and upon its cytoplasmic surface, the nuclear membrane must retain part by part a definite relation to the chromosomes whose fused surfaces it represents. As one possibility, conceive that each chromosome produces a monolayer, patterned according to its own chemical design, which serves as a template for the cytoplasmic syntheses with which we are visibly concerned in differentiation. The implications of the linear series then become important; changes of the specific pattern due to changes of the linear series could have far reaching effects. The very definition of the gene as a unit becomes difficult. The test of such possibilities can be made however: rearrangements of the chromosomes are known, and their effects are relatively slight except in the immediate neighborhood of the point of rearrangement. Yet these effects must be understood, in order

* For the benefit of those unfamiliar with genetics and its technical terms, an epitome and brief glossary are given in the preceding paper of this Volume. J. A.

to set the limits of the concept of the gene as a unit. For the proper understanding of the data, it is advisable first to consider the differentiated regions of the chromosomes and their relation to the function of the nucleus.

The Differentiated Structures of the Chromosomes

The metaphase chromosomes of small cells show little external differentiation, except for an area which lacks the staining capacity shown by the remainder for basic stains (for a review see Geitler 1938). This "primary constriction" is the region which contains the "centromere," the chromosomal organelle associated with the mechanism for the separation of the daughter chromosomes at mitosis. The centromeres are correlated in their function with the central bodies of the cytoplasm; they are connected by fibers in the mitotic spindle, and are apparently homologous bodies (Schrader 1936, Darlington 1939, Pollister 1939). Various types of experiment agree in attributing to the centromere the active movement of the chromosomes to the poles of the spindle; fragments of chromosome lacking a centromere separate, may even be included in the daughter nuclei (McClintock 1938, Carlson 1938) but form no attachment to the spindle.

It may be remarked in passing that the spindle mechanism appears to be independent of the reproductive mechanisms of the chromosomes, the contrary also being true. Thus under the influence of such drugs as colchicine or acenaphthene (for a discussion see Blakeslee 1941), the spindle is suppressed, but the chromosomes reproduce: no cell division takes place, and the reconstructed nucleus is polyploid. These effects are of interest in the study of the physiology of the centromere, in addition to their great use in polyploid study.

In the larger types of metaphase chromosome, more detail is apparent. A coiled thread, the chromonema, can be demonstrated: the extended string of genes is compressed here into a spiral (for discussions of the spiral structure of chromosomes see Geitler 1938, Darlington 1937, Huskins 1942, Kuwada 1940, White 1942). In the very largest chromosomes, there is evidence of still further differentiations: the thread of the large coiled spiral itself is contorted into what has been described as a minor spiral. This latter seems however more easily to be interpreted as the visible evidence in these chromosomes of the fundamental differentiation existing in the chromonema, into the chromomere and its interchromeric portion.

The chromomeres have been most extensively studied in the meiotic prophases, and in the giant chromosomes found in the salivary glands of the *Diptera*. They are most evident when the chromonema is maximally extended, exhibiting at this time a degree of diversity that led Belling (1928, 1933), to consider these ultimate chromomeres as the visible loci of the genes. He considered the interchromomeric substance to be non-specific, a mere connecting material between genes. This distinction, based originally on the reaction to basic dyes, is a fundamental one, and will be discussed in detail in later sections. It may be said at once however, that in their variety, their property of specific association with each other in the nuclei where pairing of homologues occurs, and their approximate number where they can be counted, the chromomeres are likely candidates for the role in which Belling cast them.

There is one especially striking differentiation of chromomeres, to which Heitz drew attention (review, 1935). Resting nuclei have long been known to contain deeply staining bodies, which Heitz proved were special parts of the chromosomes, designating them heterochromatic regions, after the similarly deeply staining sex chromosomes (heterochromosomes). Since that original definition, the scope of enquiry has widened. By analogy with inactive deeply staining nuclei, these regions were supposed to be genetically inert, and evidence of various kinds in genetic work supported the assumption. More recently, synthetic functions of a non-specific nature have been accorded these regions, and a succession of new attributes found

for them: special behavior at synapsis (Schultz 1936, Prokofyeva-Belgovskaia 1939, Schrader 1941); relation to nucleolus formation (Heitz 1931, McClintock 1934; see the review of Gates 1942); a differential reaction to low temperatures (Darlington and La Cour 1940, Callan 1942; but see also Wilson and Boothroyd 1942); and a differential reaction to X-radiation (Muller 1940, Prokofyeva-Belgovskaia and Khvostova 1939, Kaufmann 1939). These functional characteristics will be discussed below.

The distribution of heterochromatin in the chromosomes suggests a localization at centromeres and at the ends. The major heterochromatic masses are found flanking the centromere in the great majority of cases. But there are accumulating data which suggest a much more varied distribution of heterochromatic regions; indeed Kaufmann has made the suggestion that the dense chromomeres of resting nuclei (not Belling's ultimate chromomeres) may belong to this genre. In the salivary gland chromosomes of the Diptera, where the chromomeres are enormously enlarged, the heterochromatic regions generally have a vesiculated type of chromomere instead of the dense band which is set up as the paragon of excellence in the euchromatic regions. Bauer (1936) has suggested that these be named heterochromomeres; in that case however the high frequency with which such vesicles occur on occasion in *Drosophila* (cf. Bridges 1938) would lead to difficult decisions in classifying the regions in such an organism as *Drosophila melanogaster*. What the situation is in other organisms is still less clear, and one may guess that accidents of history play a large role in this distribution. Yet if this be the case, "accidents" which tend to concentrate heterochromatin around the centromere are especially frequent.

Position and Function

Against this brief outline of chromosome differentiation, the functional consequences of chromosome rearrangement can be examined concretely. When a chromosome rearrangement occurs as the result of exchange of segments, in addition to the major disturbance, the four genes at the point of rearrangement have exchanged neighbors (for an introductory discussion see Sturtevant and Beadle, *loc. cit.*). There is however a simpler situation, the tandem duplication, with a serial repetition of a chromosome segment, in which the number of exchanges of neighbor is reduced to one. These cases have proved particularly instructive; the discovery of the previously unsuspected relation between the position of genes in the chromosome and their function was made in the analysis of such a case.

The reversions to the wild type of a dominant sex-linked mutant in *Drosophila melanogaster*, Bar eye, were shown by Sturtevant (1925, 1928) to be associated with a process of crossing over whose results were unequal. One of the emergent chromosomes contained two representatives of the "mutant gene," the other contained none, and was wild type. The basis of this phenomenon became clear when the salivary gland chromosome analysis (Bridges 1936, Muller, Prokofyeva-Belgovskaia and Kossikov 1936) showed that the mutant was associated with a tandem duplication for a small section of chromosome. The apparent mutant gene could be due then to the duplication, or to the single change of neighbors, or to a simultaneous or coincidental occurrence of an intragenic change in the duplication. Further analysis was provided by the occurrence of a series of similar mutants in the progeny of X-ray experiments (Dobzhansky 1932, Dubinin and Volotov 1936, Volotov 1937, Sutton 1943). It appears from these studies that the mutant is in fact associated with rearrangements in which a specific locus in the sex chromosome is separated from its normal neighbor. The nature of the new neighbor appears to be of minor consequence. Thus the functional change depends upon a close association: the effect demands collaboration between a special pair of neighboring genes, localized at neighboring salivary gland chromosome bands.

However the original "position effect" did not concern the Bar mutant itself, but the derivatives produced by the asymmetrical crossing over. Sturtevant found that in these derivatives the departure from the normal phenotype was greater in the cases where the additional segments were accumulated in one chromosome as a series of tandem duplications, than it was in individuals with the same number of segments distributed between the members of the homologous pair. He was able in this case to perform the crucial experiment of recovering a segment from a chromosome in which the position effect had been manifested, and showing that its own intrinsic properties as a single tandem duplication, were unchanged. More recently, Rappoport (1940), in an elaborate and ingenious set of experiments, has extended the series to as many as eight segments arranged in a tandem order. He has thus been able to study the conditions under which the interaction between the successive tandem duplications, the original case of position effect, is manifest. It appears that this effect is at its maximum in the lower members of the series, the curve flattening out as the distances grow longer and other conditions of balance are operative.

Thus in the Bar case there is evidence for two kinds of position effect: one, the dependence of a gene on the presence of specific immediate neighbors for the maintenance of its effects in synthesis; and second an effect over a slightly greater distance, the coöperative function of similar genes close together. The two types should perhaps not be contrasted too sharply: both must depend ultimately upon competitions for available materials of synthesis, or accumulations of unusable reserves due to the new proximities. In any event, the question, concrete in this case, may assume the more general form: in how far can the genes be considered as legitimate separate units?

An essential datum for the answer is the distance along the chromosome over which the effects of changes in gene position are manifest. If this is a long distance, the view must be examined seriously that the pattern of the chromosome as a whole determines the specificity of its local components (Goldschmidt 1938). At the other extreme, where the distances are short the chromosome is merely the linear association of specific elements whose interrelationships depend rather upon the properties of the individual components than upon their modes of association in series.

The evidence already reviewed in the Bar case goes to show that the distances are short. Indeed the Bar mutant itself approaches the extreme: the distances are presumably the distances between genes. And in another case, the position effect due to a tandem duplication of the achaete* locus in *Drosophila melanogaster* (Demerec and Hoover 1939), separation of the responsible elements by a two band inversion has been sufficient to remove the position effect (Schultz 1941). Again the relation is one between adjacent elements.

The serial duplication of chromosome segments is apparently a rather frequent phenomenon. Thus detailed study of the morphology of the giant chromomeres of the salivary gland chromosomes of the Diptera has shown, in addition to the remarkable pattern of differentiation, a high frequency of a definite type of double band (see Painter 1941a, Bauer 1936, Bridges 1935, 1938 and Metz 1941). More elaborate repetitions of pattern are also found. The interpretation has been offered (Bridges 1935, Offerman 1936) that these are duplications of the hereditary material that have become established in the course of evolution. The occurrence of tandem duplications under experimental conditions shows that one of the processes postulated in this interpretation still occurs. It follows that the analysis of the genetic conditions within such duplicated chromomeres should throw further light on the degree to which the genes in their present form are independent units. For the high frequency of these doublets, and the occurrence of numerous cases of association of

* The achaete fly lacks certain spines or hairs. J. A.

similar mutants in close linkage as a genetic parallel, suggests that local coöperative effects may be frequent. And those established in the chromosome might obey different rules than those newly arisen.

The most complete analysis thus far is that of the Star locus in *Drosophila melanogaster*. Lewis has been able to show here that the double band (a "capsule" formed by the association of its members) contains two separable genes, one located in its right, the other in its left member. Both have similar phenotypic effects. Deficiency or inactivation of the left component (Star) changes the component at the right (asteroid) in such a way that it no longer exerts its full function in maintaining dominance over a recessive allele. Adequate crossover tests show that the effect is a position effect, demonstrating coöperative action between the members of a doublet. The maintenance of complete functional efficiency at the asteroid locus demands the action of a normal allele at the Star locus. Serebrovsky (1938) has suggested that in duplicate genes of this type, a process of complementary loss is likely to take place; modification is such that each member of the pair retains those qualities that the other loses. The result would be genes which were non-allelic by the test of heterozygosis—each containing the dominant for the other—but which would occupy neighboring loci. If this is the case, Lewis' analysis of the Star complex shows that some of these losses concern primary reactions, at the site of the chromosome. The presence of both members is necessary for the normal function of the one whose primary synthetic product is inadequate.

The observed effects in other euchromatic regions may depend upon similar upsets of coöperative systems. Yet effects of other types may be involved; relatively few of the rearrangements involve breaks within "capsules" (Lewis), but most of them show genetic changes at the points of rearrangement (for a review of the earlier literature see Dobzhansky 1936; Demerec 1939). Hence the greatest number of changes in gene function associated with changes of position do not seem to be concerned with the interactions of duplicate genes.

Our discussion so far has dealt with the euchromatic rearrangements in *Drosophila*, and the effects observed there. The picture is different in other material. In maize for example, no clear cases of functional changes at points of rearrangement have been found, although they have been looked for carefully (Stadler 1941b). The existence of so great a discrepancy raises the question of the comparability of the experiments in the two organisms. The rearrangements compared are in both cases the produce of X-ray experiments, performed upon sperm or pollen grains in which the chromosomes are in a comparable state. It is possible that the dominant lethal types may differ, and that the missing position effects in maize are the aborted embryos so frequent after X-radiation of pollen. It would, however, be an odd occurrence that rearrangements should be induced by radiation with a high frequency in both forms, leaving an excess of surviving rearrangements in *Drosophila* with position effects, and none at all of that type in maize. The question is whether there is a difference in principle between the chromosome structures or the manner of gene function in *Drosophila* and maize.

Maize is of course a plant and *Drosophila* an animal; but a case of position effect has been found in *Oenothera* (Catcheside 1939), and the rearrangements studied in mice show no changes at the points of rearrangement (Snell). A possible clue (Muller, 1941; also J. Schultz) appears in the system of pairing in maize; in contrast to the high degree of specificity found in *Drosophila*, where intimate association occurs between chromomeres in the somatic prophase, even at meiosis in maize, pairing may be non-homologous (McClintock 1933). If position effects are the evidence of specific functional relations between genes, the pairing relations are the structural results of associated specificities; and the absence of position effects in maize may indicate a correlation between the structural and functional evidences of specificity. In maize it would appear that almost any neigh-

bor will serve either to work with or to pair with; in the *Drosophilas*, the individual gene is more limited.

The discussion thus far has been confined to position effects within the euchromatic regions. Heterochromatin shows somewhat different effects; the changes in euchromatic regions which have acquired neighbors of heterochromatin extend over a greater distance than is usual in euchromatic rearrangements (Schultz 1936a,c, Demerec 1940, 1941). The functional change in these heterochromatin rearrangements frequently differs in the different cells of the developing organism, with the result that the adults display variegation for the characters dependent upon genes in the region juxtaposed to the heterochromatin. These cases will be discussed later, where their relevance to the analysis of gene reproduction will be considered. Their importance here consists in the fact that they appear to show position effects extending over longer distances than those we have considered. However the study of the variegation patterns, and other evidence, shows that these long range effects are generally exerted over a series of cell divisions. Thus the initial effect here too is a short range one; even in these cases the larger pattern of the chromosomes has little to do with the events in the separate smaller regions.

The cursory examination we have given the data of the functional changes consequent upon chromosome rearrangement is sufficient to show that the concept of the gene as an autonomous unit in the chromosome is justified by the test they impose. The interrelations between genes in the linear series are of the special sort that might be expected from a system that has developed its evolutionary history as the chromosome must have. But in these interrelations, the gross pattern of the chromosome appears to play no role discernible from the present data. Having thus the evidence that the units exist as such, we may proceed to the analysis of their relation to the visible components of the chromosomes. A simple approach to this question lies in the consideration of the means by which the genes are maintained in linear order: are the connections directly between genes, or is there an especial intergenic material having this function?

THE MECHANISM OF CHROMOSOME REARRANGEMENT AND THE MAINTENANCE OF THE GENES IN LINEAR ORDER

As has been said, the basic differentiation in the continuous chromosome fiber is between chromomere and connecting substance. Since the chromomeres have so distinctive an individuality, the temptation is great to identify the functionally distinguishable units of the chromosomes with them. In this case, the problems associated with the maintenance of linear order, and especially of the nature of the intergenic connections, concern the nature of the interchromomeric substance. But it is equally conceivable that the visible differences between chromomeres are effects and not causes. Evidently the analysis of the mechanism of rearrangement of genes, that is, the processes by which the connections between genes are broken and reestablished should prove informative.

Exchange of Parts between Homologues: Crossing over

The mechanism of the normal exchange of parts of chromosomes that occurs during most meioses, crossing over, has been the center of as acute controversies as have developed in the history of genetics. The microscopic study of the critical stages is difficult, the genetic analysis of the relevant data complex. The cytological and genetic analysis early agreed in placing the occurrence of the event early in the meiotic prophase, possibly coincident with the chromosome split (see for example Muller 1916, Janssens 1909, 1924, Wilson 1928, for some of the earlier discussions). At this time four chromosome strands are in close association, with the exchange taking place between homologous genes in two of the four strands. These exchanges have been interpreted as the cause or the consequence of the cross

shaped configurations (chiasmata) seen at the later stages of the meiotic pro-phases; at present the former view holds the field (Darlington 1937). The rationale of crossing over has been considered in two ways. Of these one has supposed a simultaneous breakage at identical points, and a subsequent fusion in the new arrangement of the paired homologues (a recent statement in Darlington 1940). The implication here is that the chromosome is a continuum, as far as reproduction is concerned, and that a mechanism exists for coördinating the break-ages so that they occur precisely between homologous genes. The contrasted point of view (Belling) derives crossing over from the mode of reproduction of the chromosome fiber. The chromosome is reproduced in two stages; the interchromomeric fibers are the products of a synthesis by the chromomeres. These are the basic self-perpetuating units. At meiosis, reproduction occurs while the paired strands are twisted about each other, the interchromomeric substances are formed between the new partners in a twisted configuration, and the resultant fiber is a crossover. At the time it was proposed the suggestion that the intergenic connections were the product of gene synthesis was a completely novel one. Its implications for the more general questions of chromosome behavior have only begun to be appreciated. Many of the issues raised at the time were special ones, connected with the calculation of crossover data, and with the cytology of chiasmata, and served to obscure the fundamental question of reproductive behavior.

At the present time, the breakage and reunion hypothesis of crossing over has been amplified by considerations of the stresses imposed upon the paired chromosomes as the result of their cycles of spiralization. In this way the attempt has been made to devise a mechanism for the precision of the breakage in both homologues (cf. Darlington 1937). The Belling hypothesis has not been re-evaluated in detail in recent years, nor have there been researches designed to test its basic assumptions. It may be said that many of the specific objections to it that were earlier urged on the basis of the genetic data, can easily be surmounted by a closer consideration of the opportunities for the postulated twists now afforded by the more recently studied cycle of spiralization.

Thus the study of crossing over affords an opportunity for the analysis of the mechanism of the maintenance of the genes in linear order, as it earlier gave the means of establishing the existence of this linear order in the chromosome. The promise is far from fulfillment, however; and yet, as we shall see, the problems already met here recur constantly in this study.

The Mechanical Breakage and Reattachment of Non-Homologous Chromosomes

While the exchange of homologous parts of chromosomes during crossing over is a regular feature of most meiotic cycles, the exchange of non-homologous portions, leading to chromosome rearrangement, is a much rarer event. Rearrangements are produced experimentally however, and much attention has been given to the analysis of their occurrence. For our present purpose, the problem is the same as that met in crossing over, with the difference that it has become more general, including all chromosomes and all stages of the cycle.

Chromosomes, like other objects, may be broken mechanically. In maize, McClintock (1938a, b; 1941a, b) has developed ingenious genetic and cytological techniques for detecting the occurrence of such breakages, and for the analysis of their characteristics. Plants containing special chromosome rearrangements provide sources of chromosomes with two centromeres. At the anaphases of the proper mitoses (in most cases the meiotic divisions) these dicentric chromosomes form bridges between the two daughter cells, bridges which are eventually broken as telophase is completed. The chromosomes at this time are under obvious tension; if the breakage were the result of the tension, it would follow that the portion broken must be the elastic component. This is known from microdissection experiments

to be the interchromomeric portion (Buck 1942). We are, however, in a less satisfactory position; for the actual breakage does not occur until the telophase, when the cell wall between the two daughter cells is formed, and may be more complex than the simple overstepping of the elastic limits.

Reattachment of the broken fragments occurs where other broken ends are present and available for reunion. Since there is no evidence at present that genes are lost at the point of reattachment, the reattachments must occur between genes. Since, however, we cannot say with certainty which of the chromosomal components was broken, it is equally difficult to say which attaches, the chromomere or the interchromomeric substance. A recent striking study by McClintock indicates that the reattachment occurs in the period of the telophasic reconstruction of the nucleus, and, in certain cases, that once this period has passed without reattachment, the broken end has lost the capacity to form attachments to other broken ends. Since this is the period of the chromosome cycle when the chromomere increase in length, and interchromomeric substance is forming, it is evident that a plausible case can be made for the importance of the interchromomeric substance in these mechanical breakages and reattachments. But the data do not as yet afford a clear discrimination, as has been seen.

Radiation-induced Chromosome Rearrangements

Our difficulties in the study of the mechanical breakages of chromosomes resulted from our failure to distinguish between tension and constriction as the immediate cause of breakage. The radiation-induced breaks present a different problem. Here the effective agents are powerful short-wave radiations, x-rays and the like. These cannot be useful in a simple discrimination between the substances in the chromosome that they affect: to a speeding electron all matter is an opportunity for energy transfer. Ultra-violet light is more delicate, and has given some information of use. But the problem is further complicated by biological considerations implicit in the techniques employed. These complications arise from the fact that the broken chromosomes observed in the experiments are usually the result of new reunions of chromosomes. In other words the nature of the initial excitation is inferred from the product of a complex series of chromosome syntheses. And the dissociation of the various steps in these processes has only begun.

The techniques for the detection of the chromosomal effects have depended upon the organism studied. Where convenient, as in *Drosophila*, genetic techniques are employed, with the advantage that the individual rearrangements are available for as detailed study as proves necessary. Under other circumstances, cytological examination of the chromosomes either in the abnormal mitoses following irradiation (e.g., Sax 1941, Marshak Carlson 1941, among others) or in the interphase nuclei of the heavily exploited salivary gland chromosomes (Bauer, Demerec and Kaufmann 1938, Bauer 1939, Kaufmann 1941) has been employed. With both techniques, the analytic procedure depends upon the type of chromosome irradiated and upon the number of mitoses between the irradiated and the observed chromosome. Thus when spermatozoa, which are a relatively homogeneous population, are irradiated, we deal with the state of the chromosomes in the sperm at the time of radiation, their metabolic state during the inactive period before fertilization, the processes which occur as the sperm head is transformed into the male pronucleus after fertilization. Furthermore, the statistics of the types of rearrangement discovered pose questions of their own: are the examined rearrangements a random sample of the events occurring in the irradiated sperm, etc.? (For recent discussions see Muller 1940, Fano 1941, Lea and Catchside 1943, Giles 1943.)

In terms of the problem with which we are presently concerned, the delimitation of gene and intergenic bond, a primary question is the relative stabilities of the two components with respect to the impinging disturbance. If for example, the gene

were more sensitive, the problem of breakage and reattachment becomes one of re-establishment of linear connections between two neighboring genes either in the presence of the debris of an intermediate destroyed fellow, or of one which while maintaining its spatial relations has lost the power to reproduce. On the other hand were the intergenic bond the more sensitive, the problems are the conditions of its regeneration. And in both cases, such factors as the initial proximity of genes adjacent to the injured link, rates of regeneration as compared with rates of separation of the adjacent members, and chances that rearrangement instead of restitution of the original sequence will occur, all enter.

It should be pointed out that the assumption has been made that the initial excitation must result in the breakage of bonds. This excitation cannot however be equated to the breakage of chromosomes: indeed, for purposes of chromosome rearrangement, where contiguity is a condition, an excitation between two adjacent strands, serving to attach them, provides a possible mechanism. Actually in the history of the subject the dominant contrasted hypotheses were the "contact" and the "breakage first" hypothesis. According to the first a single excitation sufficed to attach two contiguous strands, whose subsequent maneuvers during separation produce the observed rearrangements. Apparent single breaks are on this hypothesis explained as the result of attachment of the sister strands of a newly split chromosome. It is to be noted that the assumption that a single excitation suffices to produce an attachment is purely gratuitous: *a priori*, were the hypothesis correct, this might equally well be a multiple hit phenomenon. On the "breakage first" hypothesis, independent single excitations give rise to independent breakages of the chromosomes. The broken chromosomes reattach—and that they should do so the mechanically broken chromosomes attest—and rearrangements are formed. Thus the minimum requirement for the production of a rearrangement is two hits.

According to the "target" hypothesis of radiation effects, the number of hits required to produce a given effect can be determined from experiments in which dosage, wave length are varied. To this end a large body of data have been accumulated, particularly in *Drosophila* and *Tradescantia*, forms then in which the chromosomes when treated are quite different in their size and in the details of their behavior (Bauer 1939, Kaufmann 1941, Fano 1941, Giles 1943, Lea and Catchside 1943, Sax 1941, Muller 1940). The data show clearly that for x-rays, more than one excitation is required to produce rearrangements; neutrons, however, with a denser distribution of energy, give one hit curves. Spatial relations, movement of the chromosomes, and other factors of a similar nature have been shown to play a considerable role also. It is clear that whether or not the breaks are independent, the reattachments depend upon the availability of combining ends. And there seems also to be, according to Newcombe, some evidence for a direct effect in *Tradescantia* upon the restitution process, which complicates the analysis further.

For our present purpose, the point of chief interest is the nature of the initial disruption, and the demonstration that new connections are regenerated. Chromomeres are not usually lost at the points of rearrangement in *Drosophila*, where the analysis of the salivary gland chromosomes gives sufficient detail for conviction. Neither, as far as the evidence from a relatively elastic substance can take us, is there any interchromomeric substance lost. The picture then must be one of the destruction of intergenic connections and their subsequent regeneration. It appears that the conditions for this regeneration are optimal in the stages when the chromosomes are uncoiling to form a resting nucleus, when it may be presumed that the interchromomeric connections are growing. Thus when the condensed chromosomes of the *Drosophila* sperm are irradiated, breaks are stored, with the new attachments forming after fertilization, in the male pronucleus (see Muller 1940, also Kaufmann 1941). Similarly, a series of data from the different stages of the meiotic sequence in the eggs of *Sciara* (Bozeman 1943) show that the metaphase and

anaphase chromosomes likewise accumulate the disturbances, giving rise to many rearrangements. The earlier stages, with greater distances between the chromosomes, and opportunities for immediate restitution of the original sequences, are relatively low in the rearrangements produced upon irradiation. Apparently the most favorable circumstance for the production of rearrangements by x-rays is the subjection of a condensed chromosome for the initial effect, following which the optimum conditions for the regeneration of the new sequences are present.

The behavior of the chromosomes when irradiated with ultra-violet light is somewhat different than it is under the influence of the stronger short wave radiations. Both the genetic data in *Zea mays* (Stadler and Uber 1942) and the cytological data in *Tradescantia* (Swanson, 1942) show that the frequency of chromosome rearrangement is low, although the frequency of singly broken chromosomes is high. There is similar evidence in *Drosophila*, of a low frequency of rearrangements; no singly broken chromosomes are recovered however. Thus the changes appear to be different than those produced by x-rays, and a recent striking study of Swanson's shows a suppression of the x-ray effect under simultaneous ultra-violet irradiation. He interprets the result as evidence for a dual effect of the ultra-violet light, on the chromosome for breakage, and a stiffening (coagulation) of the surrounding sheath which prevents the chromosome movement necessary for rearrangements to occur.

The experiments upon the relative efficiency of the different wave lengths of the ultra-violet, designed to identify the sensitive component of the chromosome, have been carried out in *Zea mays*, where their genetic nature can be determined, as well as in the moss *Sphaerocarpus* (Knapp and Schrieber 1941) and in fungus spores (Hollaender and Emmons 1941), where the mutants found may or may not be chromosome fragmentations. In all three cases, a similar type of efficiency spectrum has been found, approximating the known absorption of the nucleic acids. These substances are extracted from the chromosomes, and as we shall see are responsible for the staining properties of the chromomeres. Hence the production in *Zea* of these single breaks, for such they appear to be, as the result of absorption by the nucleic acid component, indicates that effects upon the chromomeres disturb the intergenic bonds. Whether this is the result of inactivation of the terminal gene so that restitution can no longer occur, or whether the nucleic acid portion is itself intergenic, does not follow directly from the data as they stand.

GENE REPRODUCTION

As has already been indicated, the study of the disruptions and reestablishments of connections in the chromosome rearrangements leads directly to the consideration of the nature of chromosome reproduction, and hence to gene reproduction. It is commonly considered the mechanism of gene reproduction is essentially a duplication: the mother gene affords a template upon which processes analogous to crystallization take place (cf. Alexander and Bridges 1928, Wrinch 1941) or more complex transformations (Delbrück 1941). One may question how far gene reproduction is a real duplication, that is, that there is a doubling of mass followed by the separation into two equal entities. The assumption that the gene has a constant size in different cells is based partly upon the idea that a given molecular species must have a constant size, and partly upon the equality of the daughter chromosomes at mitosis. Neither of these assumptions is binding. In the world of molecules, polymers of a given species are frequent, and particularly so in the proteins. Nor do the chromosomes maintain a constant size, or even a constant number of strands per chromosome in the different tissues of the organism (see Geitler 1941, Nebel 1941, Darlington 1937 and the recent paper of Bieseke, Poyner and Painter 1942 for the discussion of various mechanisms and controversial points). It would seem that further evidence is needed before it can be assumed without question that gene reproduction is of the nature of duplication (but see Wright 1941).

It may be remarked here that various attempts have been made to estimate the size of the gene. These are estimates of the minimal size, based upon calculations of the number of genes which must be packed into a given volume (Morgan 1922, Muller 1926, 1935, Gowen and Gay 1933). The number of genes in *Drosophila* as estimated from considerations of the probability of the recurrence of mutations, agrees fairly well with the number of bands on the salivary gland chromosomes—around five thousand. The size, while it gives the order of magnitude as that of a protein macromolecule, is not a datum of sufficient accuracy to be useful for discrimination between different hypotheses of gene structure.

As has already been noted, the reproduction of the chromosomes and their separation into daughter nuclei are independent although correlated processes. It seems clear now that there is a general mechanism for the intranuclear reproduction of the chromosomes, in which all the stages of the mitotic process except the breakdown of the nuclear membrane and the distribution of the chromosomes into separate nuclei occur (see the review by Geitler, 1941). In some of these cases, usually found in differentiated highly active cells, where mitosis has been induced, the cells have been proved to be polyploid (for example, Berger 1941). In others, where mitosis does not occur, the high degree of polyploidy is inferred, either from volume relations, or from an increase in the number of heterochromatic chromosomes. In these endomitotic divisions, as Geitler has called them, the question may be raised whether all regions multiply at the same rate. Centromeres are evidently slower, and in the nurse cells of *Drosophila* it has been shown (Schultz, 1941c) that the heterochromatic regions even when removed from the centromere, lag behind the other regions. Thus although usually chromosome reproduction is adjusted so that everything comes out even, under special circumstances differences in the reproductive rates of the genes may be evident.

The origin of the giant salivary gland chromosomes has, as might be expected, been much discussed in these connections; the discussion was the stimulus for much of the development of the study of endomitosis. The original suggestion of Koltzoff (1934) and Bridges (1935) that these originate by repetitive splitting of the chromonemata without their separation was modified (Bridges 1938) to cover an increase in length over the despiralization originally postulated. Examination of the development of these chromosomes (Painter and Griffen 1937, Geitler 1938, Frolowa 1938) has shown them to be a hypertrophied four stranded structure, presumably arising by a process of growth within the original sheaths of the four strands known to be present at the final mitosis which these cells undergo prior to their hypertrophy. Whether simple splitting (duplication) or some more continuous process of synthesis at a surface occurs here is not yet clear (cf. the discussion of Painter 1941b, and of Metz 1941).

In endomitotic divisions both the chromomeres and the interchromomeric substances reproduce, and as far as can be judged, although some reserve must be maintained here, even in the more slowly reproducing heterochromatic regions, the two components keep in step. But there is another type of giant chromosome, the lampbrush chromosome so-called, found in the maturing eggs of certain fish and amphibia. These are elongate threads, quadripartite as synapsed homologues should be, with highly individualized brush-like loops (whence the name) extending out at the site of the chromomeres. Painter and Taylor (1942) have recently reported the migration of chromomeric (Feulgen-positive, see below) granules into the cytoplasm with their nucleolar products which will interest us later. One may interpret these findings as evidence for Belling's hypothesis of gene reproduction; for here evidently the chromomeres are reproducing without forming the connecting links. Their linear continuity is not maintained, and migrating as they do they are directly of use in cytoplasmic syntheses. The original four strands are maintained, and at the later stages of maturation appear as the appropriately small chromosomes of the

maturation spindle. Thus the intergenic material is restricted to the amount necessary to continue the chromosome structure into the next mitosis. The application, therefore, of Belling's dualistic hypothesis of chromosome reproduction makes intelligible the otherwise puzzling behavior of these chromosomes, interpreted by Painter and Taylor as a quite special case of "diffuse heterochromatin."

Thus the only scheme that covers these cytological data without special assumptions at present is Belling's hypothesis. It is too infrequently recognized that Belling himself based his case upon direct observation of the early stages of meiosis in the lilies: work which has not been repeated since, owing to the difficulties of observation at these stages. The clearest evidence would of course come from *in vivo* observations, and it is possible that these may be carried out using some of the more modern microscopic techniques.

Genetic techniques for the study of gene reproduction depend upon the labelling of one of the products of reproduction: the daughter cells must differ genetically, for a discrimination between mother and daughter to be possible. The frequently mutating loci in plants give numerous examples in which there are mutant spots; the plants are variegated due to a high mutation rate in the development. Demerec pointed out, in a study of the rose α gene in Delphinium, that the existence of single celled purple spots meant that the mutant change had occurred in one of the two daughter chromosomes. One might therefore infer that the mutation was associated with an error in gene reproduction—a false copy, as Haldane has called it. It is difficult to draw conclusions here, since the nature of the mutation process, attractive though the concept is, may be independent of the reproduction. There are two unknowns.

Analogous difficulties are encountered in the use of the "fractional" mutants among the radiation treatment progenies. For example, of the x-ray mutants induced in *Drosophila* sperm, one out of approximately seven appears in a mosaic individual (see Patterson 1933, Muller 1940). It has been suggested that the chromosome is two stranded in the sperm head, and only one of the two strands is hit in the sperm giving rise to the mosaic individual. The other possibility is an effect on the gene reproduction, which would provide a situation in which the products of reproduction are different. In maize, similar mosaics occur after pollen irradiation, both with x-rays and, with a much higher frequency, with ultra-violet light (Stadler 1941a, b). These differences might occur from effects on a two stranded structure in the pollen nucleus, the ultra-violet being more likely than the x-rays to break only one of the two strands. Or, again, the effect might be on the chromomere, delaying its reproduction, causing changes thereby in one of the two daughter strands with a high frequency in the ultraviolet series. As in the case of the unstable genes however, there are too many variables at the present stage for a useful discussion until more data are available.

We have already discussed the variegational translocations in *Drosophila* in connection with the extended radius of action of the heterochromatin position effect. This is due to repetition of the effect upon gene after gene at successive mitoses, until genes as many as fifty bands away from the point of breakage may be affected. The study of the pattern of variegation, where genes are involved whose changes are detectable in the same tissue, shows that the cells showing the change in the most distant gene always show a change in the genes more proximal to the break. Thus the more extreme changes are the descendants of those less extreme.

The occurrence of single cell spots in these cases permits us to apply Demerec's argument, and relate the changes to changes in reproduction. Fortunately, it will be recalled, we have independent cytological evidence in endomitotic divisions, that heterochromatic regions in *Drosophila* do have a peculiarly slow reproductive rate. And better still, the cytological examination of the salivary gland chromosomes shows a series of changes correlated with the phenotypic variegation (Schultz 1936,

Caspersson and Schultz 1938, Prokofyeva-Belgovskaia 1939). These changes occur in both the chromomeres and the interchromomeric regions; but they are graded. The first change is in the chromomere which becomes heavy and as will be seen, more densely laden with nucleic acid; more extreme changes are the gradual assumption by these originally euchromatic regions of the characteristics of heterochromatin. In the most extreme cases, where phenotypically there is a complete loss of function by the genes involved, the chromosome section can no longer be distinguished as such: it is effectively lost (Schultz 1941a). Thus the position effect of the heterochromatin may be due to an imposition of its slower rate of reproduction upon its euchromatic neighbors.

It seems likely that further study of these cases will permit a test of whether the chromomere or the interchromomeric section is the prime mover. At present it seems that the first changes are detectable in the chromomeres; but this may only be because we can see changes in them more easily. The fact that the structural changes characteristic of heterochromatin are seen in the more extreme cases, and could have been detected in the interchromomeres, does, however, reinforce the impression that the chromomere is the basic unit, and the interchromomere secondary.

The study of gene reproduction is still in its early stages, as can be seen from this discussion. Methods and material are only beginning to be available which will permit that correlation of genetic and cytological techniques necessary to establish the nature of the basic reproductive unit of the chromosome. As has been intimated, the Belling hypothesis offers a more attractive mechanism for the reproduction of a series of linearly connected units of specificity than does the duplicating split of a chromonema. How durable this attraction will be remains to be seen.

"INTRAGENIC" MUTATIONS

We have seen that both chromomere and interchromomere are associated in maintaining the structure of the chromosome, from the evidence of chromosome rearrangement. It is of interest therefore to turn to the changes which the individual gene can undergo without being lost. Instead of the unit of structure, we now examine the unit of function the gene mutation.

These distinctions are, however, limited ones. The position effects already reviewed show the high degree of integration between the intimate structure of the chromosome and the units of which it is composed. And the variegational rearrangements just discussed give evidence for a relation between the synthesis of new genes and the specific function of these genes. For, as we have seen, the series of changes in reproductive rate of the rearranged genes parallels a series of changes in function. These changes are similar to those found in "intragenic" mutants at these loci; the results of the two types of change are difficult, and in certain cases impossible to distinguish.

Thus the discussion of techniques for discrimination between structural changes and intragenic mutations is a serious one. Unfortunately, as Stadler (1932) has emphasized, there are no certain criteria. Both in *Drosophila* and in *Zea* where the most detailed studies have been carried out, it appears that extraordinarily similar effects are produced by changes that do and by those that do not have visible cytological effects (Stadler, McClintock 1938, 1941, Muller 1935). Even in the cases where a variety of changes at the same locus are available, it is not certain that the intragenic changes can be distinguished from minute rearrangements. The hope is brightest in this direction, however (Stadler 1942).

Even where no cytological changes is visible, however, there is no guarantee that rearrangement has not occurred. For a time it appeared that since ultraviolet light produced few rearrangements and many mutants, a means for discrimination

might exist here (Stadler 1941, Muller 1941). But the recent analysis of ultra-violet induced mutants in *Drosophila* (Mackenzie and Muller 1940, Slizynski 1942) shows that these also contain small rearrangements. Since these are difficult to detect even their absence is not significant. And more to the point is the question whether any *a priori* distinction is possible between intragenic change and the results of the coöperative disturbance of the effects of neighboring genes in the chromosomes—the doublets in *Drosophila* studied by Lewis come to mind. As the limiting case in any event, the intragenic change is a structural rearrangement of atoms either within a molecule, or binding molecular groups in polymeric linkages. The essence of the question reduces again to that we have already considered, the nature of the linkages between genes.

A curious aspect of the discussion of the possibility that all mutations involve structural changes has been the tendency to infer that the existence of specific separable units in the chromosome is incompatible with such a datum. We are not however as has already been apparent, faced with the paradox of Zeno; for the line in which the genes are arranged does have a local differentiation related to the specificities. And we have seen that there is a mechanism for getting a cohesive fiber out of a series of relatively independent units. Thus the fact that these units are functionally integrated, and that changes in these integrations may be the cause of mutation, does not imperil their existence as units. It should be emphasized however that it is by no means shown that intragenic mutations do not exist: it is only that there is no positive criterion for their identification.

It is evident that the study of the mutation process itself contains too many unknowns to serve, except very indirectly, as a means for the identification of the specific genic constituent of the chromosome, assuming for the moment that there is a dual system present. Since we cannot distinguish between the structural changes which involve both components of our dual system and the intragenic mutants which involve only the one, the production of mutants by radiation and the like gives information about stability but not much more. Only by a technique for the production of mutations in which it could be shown that the active agent was, for example, incorporated into a chromosomal component, does it seem likely that mutation study will give us the needed information.

In the meantime the study of the relative stabilities of different loci, and of different forms of the same locus (Timoféef-Ressovsky 1941, Muller 1941) has interest of its own. On various hypotheses concerning the nature of the gene or the intergenic bond, the rates of change from one allele to another might give useful information. The consideration of these stabilities has problems of a statistical nature. There is no *a priori* method of determining which should be the most stable condition of a particular gene, for this must depend upon the evolutionary history as well as the present state of the gene in question. This is partially the result of selection at the locus itself, by way of attainment of optimum functional efficiency; and it is also the result of selection of mutation rates in the genotype as a whole, a regulation of the overall production of the inviable mutant types in a population (see, for example Sturtevant 1937). It appears in *Drosophila* that the wild type allele is generally the least stable (Timoféef-Ressovsky, *loc. cit.*). The general picture is best interpreted both for the radiation-induced and the spontaneous mutants in terms of a disturbance of the gene followed by a return to stability, the most probable form assumed being the most stable discussion in (Schultz 1936b). There are departures from these rules in the cases of certain unstable genes, and a case of unique interest in *Zea*, in which instability of a recessive locus is conditioned by another locus in a different chromosome (Rhoades, 1941; and for a discussion of spontaneous mutation in maize see Stadler 1942).

In the disturbance of stability of a gene, there is one condition that must be fulfilled that is peculiar to intragenic mutations: the change must be of such a nature

as not to interfere with the capacity of the gene for self reproduction. This sets of course a limitation upon the possibilities for change, and increases the interest of the surveys that have been made both in maize and *Drosophila* of the types of mutational change that do occur "spontaneously." As has already been noted, each locus may exist in a variety of forms. The more delicate the tests for discriminating between alleles, the greater the diversity of alleles encountered (cf. Wright 1941, Stadler 1942, and for an earlier review Stern 1930). But the general rule appears to hold that all are concerned with the same physiological process, which in chemical terms means that a specific locus is concerned with a single type of synthesis.

Cases have been reported in which this rule appears to be contravened. In some of these it appears that nests of dissimilar genes are the answer. In other cases the answer is not so simple, and the conclusion that a single synthesis is affected seems more an article of faith. Thus the simultaneous effect at the white locus of *Drosophila*, upon the pigmentation of the eye and the shape of the seminal receptacle in the female certainly is a challenge to the discovery of some common denominator for these so apparently dissimilar characters (for a recent discussion see Dobzhansky and Holz 1943). Likewise, the connection between the intracellular effects observed in the losses of certain loci and the grosser morphological changes they occasion presents an interesting problem. Yet even in these cases it seems simpler for the present to regard the individual locus as concerned with a specific type of synthesis.

The implications of these analyses of multiple alleles for the mutation study are evident. A mutational change at a locus still compatible with its continued self-reproduction is generally of such a nature that the locus continues in the same functional category. Genes do not apparently learn new jobs with facility; or if they do, the results are fatal to the organism.

CHEMICAL ANALYSIS: THE DESOXYRIBONUCLEOPROTEINS AND THEIR DISTRIBUTION IN THE CHROMOSOMES

From the preceding, we see that the genetic and cytological analysis remove the question of the nature of the gene into the question as to which of the alternating elements of the chromosome contains the basic reproductive unit. The components are found to be so integrated that a disturbance in one results in an effect upon the other. Thus structural rearrangements give functional changes of genes; and the induction of intragenic mutations is hardly dissociable at present from an effect upon a bond between genes affecting the stability of the neighboring units.

The genetic technique, however, is not the only one available for the study of the gene even though it was necessary for the initial analysis. The chemical constitution of the chromosomes can be used to approach the problem by methods more closely allied to the conventional methods of biochemistry: the correlation of the properties of substances *in vivo* with their *in vitro* properties. As Mirsky has pointed out, the usual biochemical activity test for the gene would necessitate experiments in which an extract of chromosomes is used to make good the abnormal development in a genetically deficient individual; the potent extract coming from a non-deficient nucleus and that of a deficient nucleus proving ineffective. At the present time we are not in a position to carry out any such test. There is however a different line of evidence, provided by the unique occurrence in the nucleus of substances whose properties when correlated with those of similar substances in the cytoplasm, almost of themselves formulate rather specific hypotheses concerning the nature of the gene.

The nucleoprotein nature of the chromosomes has already entered these discussions: it is essentially responsible for their cytological staining properties. These have served to identify the components of the chromosomes associated with changes

of gene arrangement, and as we have seen the locus of a gene in the salivary gland chromosomes of *Drosophila* has been restricted to a band (chromomere) and its neighboring interband spaces. Fortunately as a result of the recent integration of chemical and cytochemical analysis, it is possible to speak with some confidence of the respective constitutions of these components of the chromosomes. They have been known for a long time, the chemistry of the nucleus having been one of the earliest growths in the histochemical field cultivated during the latter portion of the last century (see Gulick 1941, Mirsky 1943).

There are two main types of nucleoprotein, of which one is found only in the chromosomes. The distinction is most easily based upon the nature of the nucleic acid; recent data (Mirsky and Pollister 1942, 1943) support the inference that the proteins are characteristic as well. The desoxyribose nucleic acid of the chromosomes contains the unique pentose sugar, desoxyribose (Levene and Bass 1931), in contradistinction to the ribose found in the more widely distributed ribose nucleic acid. Associated with this difference is a difference in one of the component pyrimidines, the methylated form being found in the desoxyribose type. This nucleic acid, when prepared by gentle means, is an enormously long molecule, forming polymers of a molecular weight as high as a million (Signer, Caspersson and Hammarsten 1938, Hammarsten 1939, Pedersen 1940). In these long molecules the component nucleotides, phosphoric acid esters of purine or pyrimidine desoxyribose glycosides, are connected by their phosphoric acid groups. X-ray diffraction analysis of these molecules has been made, with the striking result that the distance between nucleotides corresponds almost exactly to the backbone spacing of the fully extended polypeptide chain of a protein (Astbury and Bell 1938).*

The proteins associated with the desoxyribose nucleic acids have constituted a challenge since the earliest work done with them by Miescher and Kossel. Even in their time the idea of the nucleus as a center of synthesis was prevalent, and to find the protein associated with a nuclear substance so absurdly simple as protamine was an extraordinary occurrence. Not only do they have a relatively low molecular weight but they lack completely the aromatic aminoacids which are the usual hallmark of protein specificity. Immunologically they show no reactivity unless coupled with other linkages. And yet in the sperm heads of teleost fishes, over ninety percent of the total substance present is nucleoprotein, with little evidence of other protein. It may be remarked parenthetically that a recent report describes another type of protein extract, without a clear demonstration that this does not contain nucleic acid (Stedman and Stedman 1943); until further evidence is presented it seems wise to hold to the earlier self-consistent account.

For the nucleus to contain the simplest of all proteins instead of a gallery of the most complex is a piquant situation. The genes are in the chromosomes, they control the course of development, but the substances important in the developmental sequence are complex, far more complex than the nucleoproteins analyzed. Then if these simpler substances play a part in the elaboration of the more complex ones, it must be as a pattern on which the precursors of the cytoplasmic complexities are moulded. These considerations led Kossel to the "protamine block" hypothesis of protein synthesis, according to which all proteins are built around a protamine core (see the more recent considerations of Edlbacher 1938, Block 1938). It will be seen presently that the process is more complex, and the story of protein synthesis has a leading character of nucleoprotein nature.

Quite recently, with the introduction of modern methods, the nucleoproteins of a large variety of nuclei have been extracted and studied (Mirsky and Pollister *loc. cit.*; see also Dounce 1943, Claude and Potter 1943). The proteins here are also basic proteins, the histones. More complex than the protamines, they contain

* See paper by W. T. Astbury in this Volume. J. A.

tyrosine, are larger molecular units and can form fibers. Of singular interest is the discovery of Mirsky and Pollister that these substances contain no tryptophane, although the different histones vary in other ways. In these experiments the nuclei and chromosomes have either been isolated mechanically, or a gentle salt extraction technique employed. The chromatin threads obtained mechanically are like the sperm head, over ninety percent nucleoprotein; moreover the substances removed by salt extraction agree in their properties with those obtained mechanically. In all these the nucleohistone is a protein nucleate, the two components being combined in an easily dissociable salt linkage.

We cannot as yet be sure that the nucleoproteins thus far isolated constitute the whole of the nucleoproteins of the nucleus. There is some indication (Dounce) that there may be some combined more closely, possibly with lipoids. For the question of the nature of the gene itself, the distribution of these nucleoproteins in the chromosomes themselves demands consideration.

An obvious attack is provided by the comparison of the results of extraction with the cytochemical analysis. We can correlate the localization of the substances with the functional differentiations of the chromosomes in so far as accurate chemical tests are available. The components of the chromosomes are especially favorable for cytochemical study. The strongly acidic character of nucleic acid is at the basis of the affinity of the chromosome for basic stains, and better still, Feulgen 1924 has developed a cytochemical test for the desoxyribose nucleic acids *in situ*. Most precise, in that it depends upon an intrinsic property of the substances is the analysis of the absorption spectra in the ultra-violet (Caspersson 1936, 1940c), where the nucleic acids have a striking absorption maximum at 2600 Å. This is due to their component purine and pyrimidine bases, and is quite distinct from the band at 2800 Å, present in proteins containing the aromatic amino acids. The proteins can also therefore be studied in this way, albeit with some difficulty due to their less intense absorption bands (Caspersson 1940a). They also combine with dyes, although here only a beginning has been made. Both the nucleic acids and the proteins can be digested by specific enzymes, and given the specificity of an enzyme, the breakdown of a structure by its activity can be used for the maintenance of that structure.

The major cytochemical work has been done so far with the especially favorable giant chromosomes of the salivary glands. Here it will be recalled that we are dealing with the chromosomes of a working nucleus, and it must therefore be expected that all the possible complexities will be encountered. We avoid the difficulties of the extractive techniques but now meet those occasioned by the presence of all the substances of interest at the same place, confusing possibly the accuracies of determination. Happily this is not quite the case; and for the analysis of the relation between gene and intergenic material, the chemical distinction between the differentiated portions of the chromosomes is easily made. The basic differentiation of cytology turns out to be a differentiation between segments of the chromosome relatively rich and poor in their nucleic acid content, thus a differentiation into protein and nucleoprotein segments.

The evidence for this derives from the comparison of the reactions of the segments in ultraviolet light, to the Feulgen reaction, on microincineration, to basic and acidic dyes, and to proteolytic enzymes and nucleases. It is found that the segments with a high ultraviolet absorption, shown quantitatively to be that of the nucleic acids (Caspersson 1936, 1940a) give the Feulgen reaction for the desoxyribose nucleic acids, combine with the basic dyes and show a high ash content on microincineration. The structure of these nucleic acid containing discs is somewhat disturbed on tryptic digestion, (Caspersson 1936), and nucleases remove the highly absorbing substances (Mazia and Jaeger, 1939; Mazia 1941; Frolowa 1941a).

Salt, alkali, and urea treatment (Calvin and Kodani 1941, Kodani 1942, Painter 1941b) also serve to break the linkages holding the nucleic acid to the protein component. Thus the differentiated discs must contain both nucleic acid and protein, and the intervening clear spaces contain chiefly protein.

The nature of these proteins has been the subject of study. There are apparently at least two distinguishable groups of protein present, which can be distinguished by their reaction to peptic digestion and to acid dyes. One of these, relatively resistant to pepsin, does not combine appreciably with such acid dyes as the triphenylmethane dye light green; this is the component that is easily digested by trypsin, and which forms the continuous, presumably skeletal component of the chromosomes. The other component, pepsin digestible, (Mazia 1941, Frolova 1941b), forming combinations with the acid dye, is easily dissociated from its combination with the rest of the chromosome: a slight heat treatment before fixation often suffices. It occurs on both protein and nucleoprotein segments, and is especially heavy on the fainter nucleoprotein bands (Schultz 1941c).

The ultraviolet absorption spectrum of both types of protein is known from the studies of Caspersson (1940); as might be expected, both contain aromatic amino acids. Caspersson has carried his analysis farther, with results that at present do not quite accord with the determinations made by Mirsky and Pollister on their preparations of histones. The question at issue is the locus of the absorption maximum, deduced by Caspersson to lie somewhat shifted towards the long wave lengths in the more basic proteins. In the histones prepared by Mirsky and Pollister, direct measurements show the maximum at 2750 Å, somewhat shifted towards the shorter wave lengths as compared with the ordinary proteins. This is not surprising, in view of the absence in the histones of tryptophane, with its subsidiary absorption maximum at 2920 Å. It appears from the data as they stand that the absorption spectrum of the fibrous interband space could quite properly be considered that of a histone, as judged by the extraction data. The proper interpretation of the very real shift observed by Caspersson in the regions which contain aggregations of the sheath protein is still a matter of conjecture; one may suspect histones which have now incorporated tryptophane into the molecule (see below). In any event this protein is not the skeletal protein of the chromosomes and is rather to be regarded as a chromosomal product, of the nature of the nucleolus. To this we return later.

A direct comparison of extracted materials with cytochemical analyses in the salivary gland chromosomes is not as yet available. Treatment of these chromosomes with salt solutions similar to those used by Mirsky and Pollister, causes the dispersion of the nucleoprotein within the matrix of the chromosome. In what form they would be extracted, and how closely the extract would represent the combination actually present in the chromosome, can only be conjectured. But the comparisons already made between mechanically isolated chromosomes, and the salt extracts lead one to believe that the dissolution of the structure by the salt solution does not break up the original nucleoprotein of the chromosome.

Thus the chemical evidence leads us to the view that the chromosome is a protein fiber with nucleoprotein differentiation. This differentiation has dominated our cytogenetic discussion. In itself, almost as a trap for the unwary, it suggests the hypothesis that there is a differentiation into genic and intergenic material. As a caution against too much haste, the recent analysis of striated muscle should be recalled: here also the protein fiber has nucleoprotein striations (Caspersson and Thorell 1942) and the differentiation has presumably to do with the energetics of the contractile process.* Contraction occurs in the chromosome as well, and without the detailed cytogenetic evidence, the occurrence of this differentiation need not

* The electron microscope reveals a banded structure in collagen. See paper by A. F. Prebus in this Volume. J. A.

imply any relation to the genetic specificities. Since however the previous evidence, while not conclusive, was preponderantly favorable to the idea that the chromomere, or nucleoprotein, was actually the seat of specificity, the chemical analysis is most welcome.

If it is granted that there is an intergenic material, it should be noted that it is this, and not the gene, that must form the continuous fiber of the chromosome, the material responsible for the maintenance of structure. This consideration is quite independent of our previous discussions of Belling's dualistic hypothesis of chromosome reproduction; once the intergenic bonds are synthesized, they must form the continuous element. But if this is so, the results of the digestion experiments with enzymes prove that the intergenic material must be protein, and protein of the first type, characterized by its fibrous nature and relative simplicity. Interestingly, the absorption spectra of the interband spaces agree fairly well with the description of the ultraviolet absorption spectra of Mirsky and Pollister's histones. These are themselves capable of forming fibers, and it would seem not unlikely therefore (cf. Mazia 1941) that they are at the basis of the fibrous structure of the chromosomes.

In this way we obtain a picture of the structure of the giant salivary gland chromosomes. This can be extended by a consideration of the mitotic chromosomes and their changes during the mitotic cycle. Here the search is for the substances continuous through the cycle, which on that ground would have genetic value. It is evident as Astbury (1941) has pointed out, however, that there need be no basic substance, merely a set of conditions which serve to perpetuate the possibilities of synthesis. We are not reduced to this circumstance; while there are quantitative fluctuations nucleoproteins are always present in the chromosomes. These quantitative fluctuations are significant, for by their study correlations may be achieved with the changes that occur during the reproduction of the chromosomes.

Even in Miescher's work, the concept appears that during the ripening of the sperm there is a change in the nature of the proteins; he made comparisons of the isolated spermatocyte nuclei with those of the sperm head. Later Kossel and Schenk (1928) proposed that the more complex proteins were elaborated around a core of the simpler protamine, and during the ripening of the sperm there was a converse breakdown. This concept has recently been generalized by Caspersson (1940, 1941) and brought into line with cytological concepts. According to his point of view, at the close of every mitosis, when the chromosomes form the interphase nucleus, there is the elaboration of the specific proteins used in the function of that nucleus. At this time the synthesis of nucleoprotein is held in check; but with the onset of a new mitosis, prior to the visible splitting of the chromosomes, there is a synthesis of new nucleoprotein. The metaphase chromosomes contain, on this view, the substances of the nucleoprotein bands of the salivary gland chromosomes. The interband regions are regarded as telophasic products containing the more complex proteins. The metaphase chromosomes do not however have the properties of a coalesced nucleoprotein spiral. Microdissection experiments show them to be far too elastic: there must be elastic interband spaces in the metaphase chromosome also. Thus if there is, and it seems most likely that there is, a succession of changes in the type of protein present around the chromosomes, the alternation of nucleoprotein and protein segments remains permanent. The protein characteristics dominate the interphase chromosome, the nucleoprotein the mitotic chromosome.

From the evidence as it stands no conclusion can be drawn to aid our discrimination between the protein and the nucleoprotein as the primary unit of chromosome synthesis. Caspersson (1939) has followed the nucleic acid content of the chromosomes during the meiotic prophases of the grasshopper: the maximum synthesis occurs in the very early stages before the four strands of the synapsed homologues

are evident. However, we have no comparable data for the protein components. The importance of the point is considerable; for since, as we have seen, the intergenic substance must be protein on structural grounds, the demonstration of protein fibrous outgrowths from the chromomeres assumes crucial significance.

As an addendum to this discussion, the question of the capability of fiber formation by the interband proteins may be considered. Histones have, as has been said, this capacity, but the proteins do not. Now, of all the material examined, only the fish sperm contain the protamines; but we have no data for the interphase nuclei in these forms comparable to that available in the salivary gland chromosomes. Thus it may be that the structural integrity of the chromosomes in fish depends upon the nucleoprotein. Conversely, the possibility is not entirely excluded in the histone-containing forms that fine fibers of nucleoprotein extend from one chromomere to the next, as a sort of residual template upon which the synthesis of histone took place. And if this nucleic acid continuity occurs at all, it may be basic to the chromosome structure in fish, holding the smaller protamine molecules in line.

The foregoing discussion has intentionally been restricted to the consideration of the chemical data as it is relevant to the identification of the genic component of the chromosomes. There are problems of intrinsic interest however in the chemical structure of the chromosomes. For in few places is the interrelation between the submicroscopic, molecular architecture and the visible structure of a biological system so obvious. The long rod molecules that are the nucleic acids, with their geometrical relations to the polypeptide chain, are manifest bases for the linear structure of the chromosome thread. The birefringence of chromosomes has been studied to gain evidence for the orientation of the molecules in the chromosome, and the role of the nucleic acids in this orientation has been much discussed (Schmidt 1937, Caspersson 1940b, 1941b). It has been tempting to consider the chromosomes as cables of polypeptide chains, with local differentiations imposed by the accumulation of basic groups to which the nucleic acids are attached in salt linkages (Koltzoff 1938, Wrinch 1936, Frey-Wissling 1938, and others). The intrinsic negative birefringence of the nucleic acids would then give rise to the observed birefringence of the sperm head for example, since they would serve to orient the protein in combination with them. Difficulties have arisen with these interpretations; the birefringence of the nucleoprotein bands of the salivary gland chromosomes is much lower than that of the sperm head, indeed its very existence has been called into question as an artefact (Caspersson 1940b).

Actually the consideration of the complex structure of the individual bands of the salivary gland chromosomes calls for caution in the interpretation of any observed orientation of molecules. Most of the bands which can easily be studied belong to the category of the doublets which have already been discussed. These are associated with each other as structures in which the pairing may be asymmetrical, and any intrinsic orientation may be masked. Another point that has been raised (Mazia 1941, Caspersson 1940b) concerns the degree of polymerization of the nucleoprotein in these giant chromosomes. The evidence indicates that lower polymers, which would have a lesser orienting effect, are present. This may be the result of various influences: the known effect of proteins on the depolymerization of thymonucleic acid (Greenstein 1941) could itself be enough, since the concentration of protein in the salivary gland chromosome is so high. The stricter orientation in sperm head and metaphase chromosome may be the result of the decrease in protein concentration in this type of chromosome. It seems not unlikely—a point of view that will be developed in detail elsewhere—that the orientation of the nucleoprotein molecules in the sperm head has nothing to do directly with the molecular architecture of the chromosomes, but is the expression of the long range forces found in tactoids. The sperm head may therefore be comparable to the micelles of the plant viruses studied by Bernal and Fankuchen (1941).

THE STABILITIES OF THE CHROMOSOMAL COMPONENTS AND THE
NATURE OF THE MUTATION PROCESS

The chemical data of the preceding section have shown that the skeletal substance of the chromosome, the intergenic material if it exists as such, must be protein in nature. It does not immediately follow that the nucleoprotein discs are the genes. One might conceive a dual system in which the specific function of the nucleoprotein would be the maintenance of linear order, rather than the control of cellular synthesis. This does not seem likely, since we would now have to account for the remarkable variety of the nucleoprotein bands as the resultant of action by the protein segments. These would now have to be conceived as complex, and it is presumably to the sheath protein that one would appeal for this complexity. But this type of protein is also present in the nucleoprotein bands. Thus all the visible complexity and the specific variability called for are already present in the nucleoprotein segments. Thus as regards economy of assumption, the nucleoprotein hypothesis has its advantages.

A further test may be sought in a comparison of the conditions under which mutational changes occur genetically, with those inducing changes of composition or arrangement in the proteins as far as present information carries us. Current views consider changes in protein structure as due either to the differences in the folding of polypeptide chains, or to changes in the order and the variety of the constituent amino acids. Thus whether the gene is protein or nucleoprotein, a mutational change implies, as we have seen, that either the new type of folding or the new order or composition must be perpetuated. The recent studies of protein specificity, particularly those using the delicate serological techniques, have tended to emphasize the role of the folding of protein molecules in the establishment of the specific patterns (see Pauling 1940; cf. also Heidelberger 1943). But these are specificities of the second order, developed around the pattern of folding afforded by the hapten, assuming the correctness of the Pauling theory of antibody formation as an example. In a mutation however the original pattern is altered; and if we assume that the desoxyribose nucleoproteins are all like the clupein thymonucleate of Astbury and Bell 1938b, the protein in them is completely unfolded. Hence if a gene is nucleohistone in character, the pattern of folding will not be very helpful in providing mutations; changes in amino acid composition are needed. The interband regions however with their long range elasticity may well contain folded molecules, and may enter the picture here. If, however, as has frequently been suggested, gene reproduction is two-dimensional, taking place upon a surface, we must in any case look to properties of the unfolded molecule. But all these considerations are dependent on the metabolism of gene reproduction, which is not necessarily a simple surface reaction, but involves syntheses of the nucleic acids themselves, as we have already seen and will discuss further presently.

The agents that have so far proved successful in inducing changes in chromosomes or genes are chiefly different types of radiation, all of which produce changes in the folding of proteins and some of which change their composition. The effects in the ultraviolet region, to which reference has already been made, are of most interest to us. The chief ultraviolet sensitive component of the chromosomes, judging by the efficiency spectrum for genetic effects, is the nucleic acid. As we have seen, this in itself is only a criterion of relative stability. But it is of interest that chromoproteins, when irradiated, are denatured as the result of energy absorbed by the prosthetic group, which in the present case would correspond to the nucleic acid. Thus the absorption of energy by the nucleic acid moiety of the molecule would affect the protein also. But the mutated gene cannot be regarded as the denatured protein, if we are to take this analogy seriously; for the denatured chromoproteins are no longer in combination with their prosthetic groups. Thus a process of renaturation must take place (Mirsky 1941, for a recent discussion of reversible

denaturation) for the gene to maintain its nucleoprotein nature. And it is in this process of renaturation that the specific constitutional changes must occur that give rise to the changes in function by which the mutation is recognized.

It is evident that such an analogy requires more information than we have at present concerning the reversible denaturation of the nucleoproteins; information which is difficult to obtain due to the relative lack of tests of specificity in these proteins. One may easily conceive conditions under which the renatured protein would be not quite like its original state, either in folding, or even, with more difficulty, in composition. And on such a hypothesis the state of the protein when combined with the nucleic acid does not limit the stereochemistry of the mutation process.

Some support for the view that mutations may initially depend upon a process of denaturation is found in considering the effects of other agents upon mutation. The more usual chemical techniques for the irreversible denaturation of proteins—acid or alkaline treatment, urea, etc.—are in general too drastic to permit the survival of the treated cells. There are some data (Lobashov 1937) which indicate a slight effect of an alkaline intracellular pH (treatment of *Drosophila* with ammonia vapors) and not of acid (acetic acid fumes). These effects, although quite consistent with our speculations, are too uncertain to be considered a support. Similar slight effects have also been obtained with copper and iodine treatment (Law 1938, Sacharov 1938).

More interesting are the temperature effects (Muller 1942, Plough 1941, Timofëef-Ressovsky, Delbruck and Zimmer 1935). It has been shown that the effect of temperature on spontaneous mutation is considerable. Uncorrected for a difference in developmental rate, the Q_{10} is 2.9; with the appropriate correction for the shorter developmental rate at the higher temperature, Delbruck's calculation raises the figure to 5.7. This is a temperature coefficient which approaches fairly closely that found in the denaturation of proteins; since the mutation process is a local one, restricted to the individual locus, the correspondence is of some importance. A process analogous to protein denaturation in its energetics must be at the basis of mutation.

This said, we return to our question: denaturation of which component? And the answer is ambiguous here as it was in the purely genetic consideration of the problem. In the integrated linear series, a disturbance in either component may produce a genetic effect on the other. It appeared for a time that there might be a more specific answer forthcoming from a series of experiments (Gershenson) in which it was claimed that mutations were produced by the feeding of thymonucleic acid to *Drosophila*. Repetitions of these experiments have however yielded negative results (Muller 1941). The negative result is not surprising, since many questions of technique remain to be solved before the problems of mutation in relation to the metabolism of the chromosomes can be worked with effectively. For the present we may conclude that the stabilities of the chromosomal components probably correspond to the stabilities of the genes: not a contribution of decisive value, since these same stabilities are common to most biological systems.

NUCLEAR FUNCTION AND THE NATURE OF THE GENE

Although the stabilities of the nucleoproteins are consistent with genic properties, they are not unique and so not sufficient for the analysis of the nature of the gene. But it is conceivable that the analysis of the function of the nucleoproteins in cellular metabolism might be instructive, particularly if it could be related to nuclear function. If we were to find nucleoproteins only in the chromosomes, hypotheses in which their role was considered as structural (Hammarsten 1924) or as "protective" for the active groups (Frey-Wyssling 1938) would be strengthened. But if it should turn out that nucleoproteins have roles of importance in cellular

syntheses other than those directly concerned with the chromosomes, if they can in other words be related to gene function, their relation to the gene would become closer, and together with the other evidence we have discussed, would make a strong case for the nucleoprotein nature of the gene. As it turns out, the nucleoproteins are now known to be intimately associated with the synthetic processes of the cell.

Here we are chiefly concerned with the second of the two great groups of the nucleic acids, the ribonucleic acids, and with the metabolism of the nucleus in the non-dividing, functional cell. For although we have considered the chromosomes of the interphase nuclei, we have not yet considered the composition and nature of their products in the interphase nucleus, the nucleoli. And for the consideration of the synthetic functions of the nucleus, these are of major importance. Since however the nucleoli turn out to be ribonucleoprotein in composition, our interest turns to these substances.

The ribonucleic acids differ from the desoxyribonucleic acids in the presence of *d*-ribose as the sugar, and uracil instead of thymine as one of the component pyrimidines. Their physical chemistry is only now beginning to be studied with the care and delicacy previously accorded the desoxyribose nucleic acids; some of the differences in capacity for the formation of high polymers are not so striking with improved methods of preparation (see Cohen and Stanley 1942; also Hammarsten, cited in Caspersson and Santesson 1943). Apparently, though perhaps to a lesser extent, the ribonucleic acid molecules form fibers as a result of their rod-like shape.

It was formerly believed that the ribonucleic acids were characteristic of plants, the desoxyribose type of animals. As we have seen, this is incorrect; all chromosomes contain desoxyribose nucleic acid. The error of interpretation was based on the source from which the preparations of the ribonucleic acids first came: the nuclei of yeasts are relatively small, and—the important point—the ribonucleic acids are the nucleic acids of the cytoplasm.

The evidence for this conclusion is largely cytochemical, although some separations for the analysis of cytoplasm have been carried out also (Behrens 1938). Since there is no specific cytochemical test for the ribonucleic acids, it is necessary to depend upon the concurrent use of a number of partial tests. Thus the ultraviolet absorption spectrum with a 2600 Å maximum, the absence of a Feulgen test, the presence of ash on microincineration (and more recently the development of a micro test for phosphorus (Norberg 1942)), solubility, reaction with basic dyes, all together permit a fair judgment of the presence of the ribonucleic acids. In addition, the enzyme ribonuclease, available in crystalline form (Kunitz 1940) splits the ribonucleic acids into products soluble in the usual histological fixatives. Thus the digestion followed by cytological examination has shown the disappearance of the basic stain and where it has been followed, (Brachet 1940, Schultz 1941c) of the ultraviolet absorption (Gersh). There is however still a certain ambiguity, since ribonuclease has been shown to act upon the chromosomes (Schultz) and there is evidence (Mazia, Schultz unpublished data) that the effect may be one on coagulated or fibrous proteins, causing them to go into solution once more. What the relations are here is still a matter for investigation. Nevertheless, the agreement of these various tests allows us to trace the ribonucleic acids with a moderate amount of surety.

In this way, tests have been made in a wide variety of cells, with the result that the ribose nucleoproteins seem to be as consistent accompaniments of cytoplasmic growth as the desoxyribose type is of the reproduction of the chromosomes. It appears from the comparisons that ribonucleoproteins are consistently present in considerable quantities in mitotic cells (Caspersson and Schultz 1939, 1940; Caspersson and Thorell 1941). The extreme case is to be found in the cytoplasm of the egg before the cleavage divisions have taken place: here a series of rapid mitoses must take place in a closed system such that the cytoplasm must supply quickly the

substances required for chromosome growth. In the sea urchin egg, Brachet (1937) has followed the changes in the ribonucleic acids during cleavage, and found that they decrease as the desoxyribose nucleic acid content rises. In the rather different systems in the meristematic tissues of plants (Caspersson and Schultz 1938) and the embryonic tissues of animals there is a similar ribonucleoprotein cytoplasm. But, and especially so in view of Brachet's data, a relation of the ribonucleoproteins to mitosis does not itself satisfy the requirement we have set up, of a relation of the nucleoproteins to syntheses of various types in the cytoplasm. They might simply be part of a reciprocal system for the multiplication of chromosomes, and have no necessary relation to the genic constituents. From the evidence already presented this would seem improbable, but conceivable. It can, however, be excluded.

Studies of cytoplasm in which other synthetic activities are occurring show that preliminary to the production of the particular synthetic product there is an accumulation of ribonucleic acids in the cytoplasm. For example, in the growth of a yeast cell it has been shown that the first activity when a nitrogen source is supplied, is the multiplication of the ribonucleoprotein system. Still better is the evidence in secretory cells. Here the formation of the protein secretory product, for example in the pancreas, is preceded by a synthesis of ribonucleoprotein in connection with nuclear activity (Caspersson, Landström-Hydén and Aquilonius 1941). Similar relations have been found in the studies of the nerve cell (Landström-Hydén 1942; but see Gersh and Bodian 1943). And other cases could be added. On this evidence, the conclusion seems fair that the ribonucleoproteins are concerned with protein synthesis at least, and very likely with synthesis in general. The exact *in vitro* implementation of these cytochemical facts has only begun: we know for example that many of the respiratory enzymes are nucleoprotein, of a special kind it is true, but dependent for their activity upon a nucleotide in combination with a protein. And some nucleoproteins have a phosphatase activity, of a kind which has already been suggested in other connections to have a use in the development of chemical theories of protein synthesis (Stern 1942).

Thus in a preliminary way the argument for the importance of the nucleoproteins in the cell can be based upon functional as well as structural grounds. It would be pleasant if the analysis of the intermediary metabolism of the development in gene differences—such studies as those of the anthocyanin pigments of plants, the growth factors and amino acid metabolism of *Neurospora*, the eye pigments of insects, to name a few representative cases—could be correlated with these discussions. Unfortunately, the analysis of these specific syntheses controlled by genes has not yet proceeded far enough: in none of these cases has the synthesis of the enzymes postulated to carry out the transformations observed been studied as yet. Thus they give us no present guide, since the primary chromosomal reactions must be prior to the synthesis of these enzymes; the enzymatic activities of isolated nuclei are rather restricted (Brachet 1939, Behrens 1939, Dounce 1943). But as has already been intimated, the primary chromosomal reactions are visible in the formation of ribonucleoprotein bodies, the nucleoli.

All of the early theories of nucleolar function associated these bodies in some way with the synthetic functions of the cell, either as reserves, by-products or precursors (cf. the review by Gates, Caspersson and Schultz 1940, Caspersson 1940, 1941). The cytological analysis shows that these bodies have their origin at special heterochromatic regions of the chromosomes (Heitz, McClintock, and others). Thus we have here the association, intriguing in view of the discussion of the cytoplasmic nucleic acids, between the massive desoxyribose nucleoprotein regions of the chromosomes, and the ribonucleoprotein products. This gives a functional basis for ascribing importance in the chromosomes to the nucleoproteins. For we have here the topographical evidence of a link between the nucleoproteins that are characteris-

tic of the chromosomes and those that are the characteristic cytoplasmic accompaniments of synthesis.

The topographical relation implies a reaction sequence of these related substances that is the converse of that found by Brachet in the cleavage of the sea urchin egg: thus nucleoprotein synthesis involves, as it should, both nucleus and cytoplasm. But by integrating this approach with the genetic technique, it is possible to show that the pattern of the cytoplasmic nucleoprotein synthesis is set by the nucleus. In the earlier literature there was much discussion of actual transfer of substances from nucleus to cytoplasm, the thought being that the substances of the chromosomes themselves were so transferred. The desoxyribose nucleoproteins are however restricted to the nucleus in all but exceptional cases. The mechanism is a different one, made evident in the accumulation of ribonucleic acids around the nuclear membrane (Caspersson and Schultz 1940, Landström-Hydén 1942, Caspersson 1940a) in cells where this synthesis is taking place. In some cases there is a visible migration of ribonucleoprotein nucleoli (Painter and Taylor 1942) associated with desoxyribose nucleic acid granules; in others the sequence is not so clear, and the interpretation (Caspersson) has been that precursors pass through the nuclear membrane forming the ribonucleic acids in the cytoplasm. The difference is probably the size of the particle migrating, since in the case described by Painter and Taylor there are many small nucleoli, whose origin has been ascribed to diffuse heterochromatin instead of the massive blocks that are the rule. What is implied is essentially the hypothesis that all nucleolar substance is the product of heterochromatin; and more than this, that the function of heterochromatin is the regulation and synthesis of the ribonucleoproteins of the cell.

The peculiarities of heterochromatin have already entered our discussion earlier, particularly in connection with gene reproduction. In the salivary gland nucleus of the *Diptera*, special "heterochromomeres" are associated with nucleolus formation. It should be noted here that their staining reactions and behavior in digestion experiments are not dissimilar to those of other chromomeres, except perhaps for a greater variability in nucleic acid content. They do differ in their mode of association; the different heterochromatic regions tend to associate with each other, being coalesced into a "chromocenter," in which the usual regularities of the interband regions of the chromosomes are not apparent. This apparently characteristic difference of synapsis may however be spurious, since rather similar pictures occur in the behavior of the tandem duplications already encountered. In fact an early hypothesis (Muller and Prokofyeva 1935) held that the heterochromatic regions themselves consisted of such duplications. Thus the indiscriminate synapsis would be the result not of a difference in principle between the behavior of the heterochromatic and the euchromatic regions, but rather of the extensive duplication of the former. It is not however easy to reach a decision at the moment, until we know more about the behavior of heterochromatin in chromosome reproduction. For with the slower reproductive rates shown by these regions in the nurse cell endomitoses already discussed, a consistent application of the hypothesis of interband prediction by the nucleoprotein bands leads to the inference that in a system like the salivary gland chromosome, in which separation does not take place and pairing is maintained, a difference in the interband structure might be one way in which the slower reproductive rate could manifest itself. Conversely, it might be argued that one reason for the slower reproductive rate is an inability of the heterochromatic regions to synthesize the fibrous interbands on time. Arguments have been raised however, on evolutionary grounds, for inferring that the gene contained in small duplications "degenerate" (Offerman 1935, Serebrovsky 1939, Muller)—meaning essentially that they lose their specific functions by mutation, and that the resulting mutant genes contain in the extreme case only the non-specific reproductive functions

common to all genes. Thus the heterochromatic regions would be considered as containing genes which, whatever their initial character, have now reached the lowest common denominator of the gene—self reproduction and the non-specific gene product. On this view the nucleoli, which for example are formed at all loci in the lampbrush chromosomes, need not necessarily be the products only of the heterochromatic regions. They may, as indeed McClintock has suggested, be formed all along the chromosomes, and be collected at the nucleolar organizer near the major heterochromatin. More information concerning the genetic properties of heterochromatin will help in clearing up these questions; their importance at the moment is in the clarity with which they present the immediate problems to be dissociated in the analysis of the function of the gene. If the heterochromatic regions and the nucleoli are really to be compared with gene and gene product, the composition and function of the nucleoli are data of first importance. Thus the effect of changes in heterochromatin—the genetic technique—upon the composition of the nucleoli becomes a useful approach.

We are not limited in our information concerning the nucleoli to the qualitative content of ribonucleic acids; the absorption spectra have given information concerning the protein as well. Moreover in the salivary gland chromosomes local aggregations of material similar to the nucleoli occur at many places in the chromosomes (minor heterochromatic regions presumably). Caspersson has compared the absorption spectra of these regions associated with heterochromatin, and finds them all to exhibit on analysis the characteristic shift of the protein band to the longer wave lengths that he has defined as indicative of the histones. Whether or not the comparison of these non-fibrous substances with Mirsky and Pollister's histones is correct, is questionable; they correspond in their properties (pepsin digestibility, staining, etc.) to the somewhat more acidic sheath proteins already discussed. It may be that they are histones into whose molecule tryptophane has been introduced; analysis of nucleolar protein by extractive methods would be desirable. The interest is considerable in the fact, which should be emphasized, that these absorption spectra occur characteristically in the presence of the ribonucleic acids. These may be proteins as distinctive in their combination with the ribonucleic acids as the histones and protamines are with the desoxyribonucleic acids.

In *Drosophila*, changes of the composition of the nucleoli have been shown to accompany changes in the proportion or the arrangement of the heterochromatic regions (Schultz, Caspersson and Aquilonius 1940). There are obvious changes of the relative amounts of nucleic acid and protein, and may even involve the composition of the protein making up the nucleoli. We have thus direct genetic evidence for changes in the genic function in heterochromatin affecting the ribonucleoprotein structure. There are as yet no analyses sufficiently detailed as to permit of an estimate of possible significant variations in the composition of the different minor aggregations of sheath material ("puffs" or minor nucleoli). Such analyses when they are forthcoming will provide direct evidence concerning specific differentiations in heterochromatin. Since the changes of composition in the nucleolus itself are so varied, the results should prove of interest. But already the contribution to our discussion is clear: the nucleoproteins important in cytoplasmic synthesis are shown, within the nucleus, to be influenced by genetic changes in the chromosomes.

The argument can be carried a step farther: having changed the conditions in the nucleus, is there evidence for a concomitant change in the cytoplasm, of the sort to be expected from the aggregations of ribonucleic acid around the nuclear membrane. Increases of heterochromatin in the nucleus should have an effect on the cytoplasmic nucleic acids and the processes they are concerned with. One case of the kind already exists: the heterochromatic Y chromosome, present as an additional chromosome in the female *Drosophila*, increases the concentration of cyto-

plasmic nucleic acids in the egg cytoplasm (Caspersson and Schultz 1938). The functional changes correlated with this cytoplasmic effect we have met before. They are the changes in gene reproduction effected by heterochromatic regions on their neighbors in translocations.

The severity of the effects in these variegational translocations is strongly affected by the heterochromatin present elsewhere in the nucleus: the addition of a Y chromosome induces, in many cases, a return to the normal condition both in the adult characters affected and in the correlated nucleoprotein changes of the salivary gland chromosomes (see Gowen and Gay 1934; Schultz 1936a, c; Dubinin and Heptner 1935; Prokofyeva-Belgovskaia 1939; Panshin 1938). Important for our present case is the discovery of Noujdin that a similar, though somewhat slighter effect can be mediated by the cytoplasm synthesized under the influence of the additional Y chromosome. Thus the presence of the additional cytoplasmic nucleic acid, or rather ribonucleoprotein, has an effect on the character of the embryonic mitoses in *Drosophila*: the effect of the Y chromosome in restoring to the normal condition gene reproduction near heterochromatin, is paralleled by its effect on the nucleoproteins, which, we must still infer following Brachet and the sea urchin, have their influence on the early cleavages. And it is their effects that are visible in the variegation suppression.

We have found, then, a system in which there is evidence of an interrelation between the ribonucleoproteins of the cytoplasm, the desoxyribose nucleoproteins of the nucleus and the degree of function of special genes at given loci. It will be remembered that the initial change was a change in the desoxyribose nucleoprotein on the translocated band. The analysis has not yet proceeded far enough to show whether sheath protein or skeletal protein of the chromosomes is primarily affected by this desoxyribose nucleoprotein change. The increase in nucleic acid is characteristic for non-functioning nuclei, and here obviously to the malfunctioning genes. An abnormality of sheath protein, an inhibition of the normal fibrous component which according to Belling's dualistic hypothesis must be synthesized by the nucleoprotein gene, would be to the point; similar to the discussion previously of the delayed reproduction of heterochromatin itself. The relation to the cytoplasmic nucleic acids is in accord with the idea of a reciprocity between cytoplasm and nucleus previously met in the general discussion of the function of the cytoplasmic nucleic acids. Here however, we have it influencing, by way of the reproduction of the genes, their specific function. In the variegated races, the initial effects are due presumably to the imposition upon the translocated genes of the slower rate of the heterochromatin; with the increased cytoplasmic ribonucleoprotein, the general rate is increased and the imposed delay avoided. It may be that similar relations are involved in the effects of supernumerary heterochromatic chromosomes upon polyploidy in the pollen grain of *Sorghum*, as Darlington and Thomas (1941) suggest, although as yet we are provided with no data concerning the cytoplasmic nucleoproteins in this case.

The considerations of the present section have been rewarding. Although the field is still in its infancy, the functional importance of the nucleoproteins in synthesis is demonstrated. If the nucleoproteins of the chromosomes are not the genes, they are so closely associated with them that they are not distinguishable by any simple means. But we have still to consider an argument of another type.

NUCLEOPROTEINS, VIRUSES AND GENES *

We have preferred in our discussion thus far to avoid arguments from analogous self-reproducing systems; it seemed useful to determine whether the evidence of the chemical nature of the gene could be made convincing by the use of the data in the

* See "The Colloid Chemistry of Purified Viruses," by M. A. Lauffer and W. M. Stanley in this Volume. J. A.

field. But having reached a conclusion, it is of interest to test it by comparison with systems which, lacking the structural linear order of specificities in the chromosomes, nevertheless do have the property of self-reproduction. For the genes, the viruses provide the test case. And the demonstration that these are nucleoprotein in nature reassures us. In fact not only the viruses and genes but also the remaining self-reproducing element in biological systems, the plastids (Menke 1938) contain nucleoprotein. The basic reproductive units of living matter are the nucleoproteins.

Both genes and viruses, to return to the analogy, have the property of self-reproduction (Muller 1922). Similarly both mutate. These would appear to be a distinction in that genes influence specific syntheses in the cytoplasm. However the syndrome that accompanies the virus disease often mimics the effect of a gene mutation. The difference would appear to lie in the fact that the virus syndrome is due to the multiplication of the virus at the expense of the host; the mutant effect is due to the inability of the organism itself to provide the full complement of syntheses.

The point of importance in the present discussion is that these simplest self-reproducing units are composed of ribonucleoprotein (Bawden and Pirie, Stanley 1941). Comparisons of the different strains show that the presumable mutations which result in their differentiation involved in some cases at least a change in their amino acid composition (Knight and Stanley 1941). We deal here with proteins more complex than the histones and protamines, more like (although at present more thoroughly analyzed than) the cytoplasmic ribonucleoproteins. Thus the parasitic self-reproducing bodies are ribonucleoprotein.

Apparently then the unique property of the genes from the present point of view, is that in addition to performing their own autosynthesis, they provide the substances important for other cellular syntheses, the ribonucleoproteins. Systems containing the desoxyribose nucleoproteins are the only ones which are not obligatory intracellular parasites. Thus the ribonucleoprotein viruses may be regarded as competing in the cell for the products of nuclear synthesis. It is extraordinary to consider the simplest of all proteins setting the conditions for the production of the most complex. By this technique they have extended their environment: the simple nucleohistone has the capacity, by setting up hierarchies of synthesis, both to buffer itself against the outside world and to use it more efficiently. The primordial evolutionary step, one may guess, involved the invention of the reciprocal desoxyribose and ribonucleoprotein system.

Colloid Chemistry in Embryonic Development

L. G. BARTH

Department of Zoology, Columbia University, New York City

In a sense, of course, the colloid state is the basis of all living processes, since without it there can be no life. However, this is such a broad generalization that it is of little use, since in some *particular* processes, such as organization, the colloids may not be important. What we are trying to show here is that changes in colloidal units are not only important but fundamental in making organization of the egg possible.

Introduction

The development of an egg or of a mass of undifferentiated cells is a problem involving *quantitative* chemical and physical differences in the protoplasm, such as concentration, activity, rate of diffusion, etc. There is no indication from experimental work that *qualitatively* different chemical substances are responsible for the *early* stages of differentiation. Thus, generally speaking, all parts of an egg may be stimulated to form all structures, and therefore *all parts* must contain *all* the substances necessary for development. What, then, causes the parts of a developing system to form into different structures—into an organized embryo? Since homogeneous distribution of the contents of a system would render any development impossible, it must be to some extent heterogeneous; this heterogeneity must occur in the physical and chemical state of the substances in various parts of the developing system. In some parts a substance may be bound, so that it is not reactive, while in other parts it may be free. Or, a substance may be very finely dispersed and highly reactive, or very coarsely dispersed, and only slightly active.

An increase in chemical activity could be brought about by selective adsorption of prosthetic groups upon the large protein molecules forming an active catalyst area. Similarly, elution of prosthetic groups from a catalyst would reduce activity. This adsorption or elution would be controlled by the chemical milieu of the catalyst (Alexander, 1939). A shift of the prosthetic group from one protein to another would form an entirely new catalyst.

With parts differing only in rate of chemical activity, a developing system would become essentially a series of processes in steady state, involving *sources*, such as oxygen and substrates, and *sinks*, such as carbon dioxide and diffusible metabolites. The overall rate of these processes is governed by the activity of the enzymes which catalyze the various steps in the processes. Since these enzymes are proteins, or proteins plus prosthetic groups, the velocity of the reactions will depend upon their degree of dispersion and on the contact relations of enzyme and substrate. In the case of enzymes with prosthetic groups, the catalytic activity is also controlled by the degree of dissociation of the combined enzyme-prosthetic group, since it is only the combined product which exhibits activity.

Fertilization

The stimulus for development involves a change in the rate of chemical processes in the egg through some internal rearrangement. No special compounds have to be added to the system to produce this change, since the action of the sperm can be

duplicated by a large variety of physical and chemical agents. Therefore we must look for a release (or binding) of substances already present in the egg, or an increase (or decrease) in the chemical activity of substances through changes in degree of dispersion or in percentage of adsorption, or in the nature of catalytic areas. Release of substances could be brought about by removal of lipoids from the surface of particles, thus bringing them into contact with the aqueous phase of protoplasm. Changes in dispersion and adsorption could be effected by changes in pH, alteration of the salt balance, and by special organic compounds.

The various factors in the stimulation of the egg were crystallized recently by Heilbrunn (1940) into a general theory of stimulation. The essential factors involve (1) agents which release calcium ions from a bound form in the surface or cortex of the egg, and (2) the action of this increase in concentration of free calcium on the internal protoplasm.

That stimulation results in a release of calcium from the surface of the cell is shown by the formation of calcium oxalate crystals in the cell after treatment with various physical and chemical stimulating agents. Furthermore, an increase in the viscosity of interior protoplasm can be detected after stimulation, and this is consistent with the effect of increase in concentration of calcium. Finally, typical calcium-binding ions, such as citrate and oxalate, will prevent stimulation, presumably by precipitating the free calcium.

The origin of the free calcium upon stimulation is the cortex of the cell, which contains calcium in bound form. If this bound form of calcium is a lipo-protein complex, it becomes easy to explain why such a wide variety of agents act as stimulators. Any agent which acts upon either the protein fraction or the lipid fraction could release calcium and elicit a response, if the calcium is set free to act upon the internal protoplasm.

The reaction of the protoplasm of the egg after stimulation involves a number of changes which appear to be in part colloidal. In some cases a sudden increase in the rate of oxygen consumption occurs, indicating an activation of catalysts. According to recent findings (Ballentine, 1940), the changes in the rate of oxygen consumption are governed by change in the active concentration of the dehydrogenase of the egg. Such a change should be detectable optically, and indeed Runnstrom (1928) has observed a change in the degree of dispersion of the colloids in the cortex of the egg. More recently Moser (1940) has demonstrated that certain visible granules in the cortex of the egg dissolve (or at least become invisible) a few seconds after the sperm penetrates the egg.

The manner in which the normal stimulating agent in the sperm is introduced into the egg cell involves a number of colloidal phenomena. In the first place the egg liberates a substance, fertilizin (Lillie, 1919), which acts upon the surface of the sperm so that a reversible agglutination of the sperm heads occurs. Likewise, the sperm contains a substance, egg agglutinin, which produces a solvent action on the jelly and surface of the egg (Frank, 1939). These two substances are colloids, probably proteins, and will react with each other in a test-tube, with the result that both become inactivated. Thus a mixture of the two will agglutinate neither sperm nor eggs. The exact role of these substances is uncertain, but that they aid in fertilization is likely (Tyler, 1941).

Differentiation

The response of the egg after stimulation is a series of colloid chemical changes which lead to differentiation, or the formation of different structures from the parts of the egg. It seems quite clear now that the various parts of the egg do not contain any special chemical compounds which act as differentiating factors. Rather it becomes more and more certain that *all* parts of the egg contain *all* of the *basic* chemical constituents for *all* parts. The fact that all parts of the egg can be made

to form all structures must be the starting point of any attempt to interpret development on a colloidal basis. For colloids, by exhibiting a great range of dispersion and adsorption, can thus show a wide range of chemical activity, even when present in the same concentration throughout the egg. A respiratory enzyme present largely in the form of coarse granules would possess a rather low activity compared with the same amount of enzyme more highly dispersed. For example, the dehydrogenase activity of the fertilized sea-urchin egg is five times that of the unfertilized egg, yet there appears to be no change in the *quantity* of those compounds already present in the unfertilized egg, but only a change in their *activity*.

These changes in colloid state are important in other phenomena. The reducing activity of the egg is highest at the animal pole,* and lowest at the vegetal pole; the former normally develops into ectoderm while the latter forms endoderm and mesoderm. However, this difference is not caused by presence or absence of special substances, since the animal (ectoderm-forming) half of the egg can be converted into endoderm and mesoderm by treatment with lithium chloride. Similarly the vegetal half can form ectoderm. It is not reasonable to assume that lithium chloride forms some special substance necessary for the formation of mesoderm and endoderm in the animal half, but rather that it modifies the substances already present by altering their degree of dispersion or catalytic activity. The difference in reducing activity between the two halves of the egg clearly indicates a difference in chemical activity of the enzyme-substrate relationship in respiration. This difference could be caused by differences in the degree of dispersion of dehydrogenases, or in degree of dissociation of prosthetic groups from proteins, and this in turn could be modified by the action of lithium chloride.

In this connection Child (1941) has stressed in his theory of development the quantitative differences within the egg, which can be demonstrated by a variety of methods. These quantitative differences frequently are expressed as differences in the rate of metabolism which can be measured. Ultimately, of course, these give rise to differences in chemical constitution, which finally result in chemical differentiation of parts. Qualitative differences may also follow specific catalyst changes due to adsorption or elution of specific prosthetic groups.

The conversion of a mass of cells into various structures arranged in orderly fashion in space and time has been termed *organization*, and the factors responsible for the change are termed *organizers*. The organizer may be contained in a particular group of cells, and the structures then arrange themselves with respect to this locus. Since we encounter various levels of organization it is well to classify developing systems with regard to complexity of organization.

1. **Labile systems.** These groups of cells form a chemical system which is very susceptible to change. As a result, external agents of various sorts can act as organizers and bring about a complete rearrangement of structures. The coelenterates are striking examples of such a system. The egg of *Fucus* is another outstanding case where the center of organization can be completely changed by a variety of external agents (Whitaker, 1940).

2. **Semi-labile systems.** In these masses of cells the organizers are more stable, and external agents as a rule do not act as organizers. A more drastic action is necessary to change the organization in these forms. The sea-urchin egg is a good example.

* Eggs are for the most part spherical, and it has become conventional to distinguish two poles of a diameter as markers of one polarity of an egg. Thus the point at which the polar bodies of the egg form is termed the animal pole, while the opposite pole is the vegetal pole. The hemisphere from the equator of the egg to the animal pole is called the animal half; the remaining hemisphere the vegetal half. The protoplasm around the animal pole usually forms the outer layer of the embryo, the ectoderm, while that of the vegetal pole usually forms the mesoderm, giving rise to muscle and connective tissue and also the endoderm of the gut.

3. Stable systems. Some forms appear to be unaffected by external agents, which suggests that the organizers are very stable, and as yet no adequate means of reorganization has been found. Typical examples are the eggs of annelids and molluscs.

Labile systems. We shall use the stems of *Tubularia*, a marine coelenterate, to show the characteristics of this kind of organization. In the first place, we find that all parts of the system are capable of developing into an organized structure, so that no difference in chemical composition can account for organization proceeding at one locus as compared with no action at other loci. Yet, since quantitative differences in the rate of regeneration are observed along the length of the stem, there must be differences in the rate of chemical reactions which govern the rate of regeneration. This again leads us to the necessary assumption that the chemical compounds are present in different states of aggregation or adsorption resulting in differences in catalytic activity.

The second characteristic is the ease with which a structure is organized from a group of cells. For wherever a cut is made so that the cells are exposed to sea water, a hydranth will form. Now this exposure of the cells to sea water does two things: (1) it provides a better supply of oxygen, and (2) it allows excretions to be carried away faster. The effect of change in the supply of oxygen can be seen from studies showing the rate of regeneration as directly dependent upon oxygen tension. Thus it can be seen that the higher the oxygen tension the more rapidly regeneration or organization proceeds.

The effect of accumulation of excretions and carbon dioxide is to inhibit organization. Thus cells at a cut surface will tend to organize into a hydranth because of a relatively high oxygen/metabolite ratio. There is then a dual effect—a stimulation due to increased supply of oxygen, and a release of inhibition caused by a faster removal of metabolites.

The mechanism of the action of a relatively high oxygen/metabolite ratio upon cells at the cut surface is suggested by studies on the relation between oxygen tension, oxygen consumption and the rate of organization. First, the rate of oxygen consumption is highest at the apical end of the stem, and it is at this end where cells organize into a hydranth. Second, the oxygen tension determines the rate of oxygen consumption. Thus at the exposed surface of the stem, where the oxygen/metabolite ratio is highest, the oxygen consumption will also be highest. As we go deeper into the stem from the cut surface, the oxygen/metabolite ratio will be progressively lower and lower (which means that the oxygen consumption drops off), until we come to regions where it is too low for organization. Between this latter region and the cut surface there will be intermediate regions where various degrees of organization will be possible. It may be that these different degrees of organization are expressed as different structures, so that the mouth forms at the region of highest rate of oxygen consumption, the oral tentacles at a somewhat lower rate, the basal tentacles at a still lower rate and finally the base of the hydranth at the lowest rate.

Why these differences in organization due to differences in rate of oxygen consumption should arise follows from the study of dominance (Child, 1929). In studies of this phenomenon we find that when two groups of cells are competing with each other, only the higher metabolizing group is able to organize into a hydranth. This dominance of the more active group of cells over the less active appears to be a competition phenomenon, whereby more rapidly metabolizing cells remove materials from slower metabolizing parts. For, when the circulation between the two groups of cells is blocked, the slower-metabolizing group is able to organize into a hydranth. In this way the competition between two groups of cells can determine whether or not they are able to organize into structures (Barth, 1940).

This same phenomenon may be applied to the orderly arrangement of the parts of the hydranth. Given a sufficiently high oxygen/metabolite ratio for the organization of a hydranth, then, within this group of cells, part A will be metabolizing faster than part B. Therefore, B is not able to develop into the same structure as A, since A is removing materials from B. B then forms some other structure. Similarly, B is metabolizing faster than C, and so C under the competitive action of B forms a different structure. Generalizing, since the metabolism of $A > B > C > D \dots$, the structures which develop will be such that $A \neq B \neq C \neq D \dots$. We have essentially a competition between the chemical reactions whose velocities are different.

Here the colloidal dispersion of enzymes operating in metabolism must play an important role for, as pointed out earlier, the rate of oxygen consumption varies along the stem. This could be explained if the activity of the enzymes simply decreased with time, since the younger regions respire at a higher rate than older regions. This difference in activity results in a gradient in metabolism such as outlined above, and forms a system which will organize into a hydranth. However, this difference in activity in enzymes is easily obliterated, since exposure to high oxygen/metabolite ratio can speed up metabolism locally and set a new locus for organization. We see that there exists a labile determination or organization in the stem, but that this labile organization is not so important as organization imposed by the oxygen/metabolite ratio. In other systems we will find that the internal organization is more fixed and that external factors do not change it so readily. However, in these semi-labile systems the internal organization appears to be the same as in the very labile system of *Tubularia*.

The egg of the marine alga, *Fucus*, presents a very labile system, since a rhizoid can form from any part of the cell. This again shows that the basic materials of the egg are uniformly distributed and that only the activity of these materials can be responsible for internal organization. The activity is very easily controlled by a variety of agents, so that temperature and pH gradients, ultraviolet light, and centrifugal force are able to direct the outgrowth of the rhizoid (Whitaker, 1940). These agents in some way increase the activity of an auxin, which causes elongation of the cellulose wall of the egg. However, it becomes difficult to explain the action of these diverse agents as directly affecting auxin, so that an indirect effect on the mechanism of auxin production becomes necessary. It will be noted that some of these agents, pH and ultraviolet light, would be expected to change the activity of enzymes producing auxin while others, like temperature, would have a direct effect on auxin activity.

Semi-labile systems. How does this concept of competing reactions apply to more complex systems, such as the egg of the sea urchin? As early as 1916, Child gave evidence to show that the factors bringing about organization were quantitative in nature. Later (Child, 1940) these ideas were confirmed and extended. Runnstrom (1933) similarly has advanced the theory of quantitative factors as responsible for differentiation. While the two ideas are not entirely in agreement, the essential part of both is (1) that no qualitative differences exist within the egg, and (2) that a quantitative difference of some kind governs organization.

These quantitative differences again must trace back to differences of activity and not to concentration of enzymes. For, in the whole egg, the animal portion is said to develop into ectoderm because of a predominance of animal factors, while the vegetal portion forms mesoderm and endoderm because of the presence of vegetal factors. However, the full complement of vegetal factors must be present in some state in the animal portion, because this latter may form a whole embryo under certain conditions. Similarly, the animal factors necessary for organization must be present in the vegetal portion, since it also can form an entire embryo. Obviously, then, the basic chemical composition of the two portions must be identical, although in normal development they form vastly different parts of the embryo. Since the

chemical composition is the same but the development is different, there remain only variations in colloidal or physiochemical state to explain the difference in behavior in the animal and vegetal portions of the egg. This could be a difference in the adsorption of free prosthetic groups of cellular catalysts.

What is the consequence of these quantitative differences? In the labile systems they were shown to be expressed as differences in rate of respiration. Child (1936) demonstrated that in echinoderm eggs the ability to reduce methylene blue is greater at the animal than at the vegetal pole. Since methylene blue is a hydrogen acceptor, it is a good measure of dehydrogenase activity, and therefore the evidence indicates that this activity is measurably higher in the animal portion of the egg. Given this difference in rate of reduction between the animal and vegetal parts of the egg, we can apply the concept of competing chemical reactions, as developed under labile systems, to the organization of the sea-urchin egg. This greater dehydrogenase activity of the animal portion during the formation of ectoderm removes from the sphere of action substances which may be utilized by the vegetal portion. The lowered concentration of these substances in the vegetal portion then causes this part to form endoderm and mesoderm, possibly through selective adsorption, forming new catalysts. Experimental procedure shows that, when the animal portion is removed, the remaining vegetal portion forms an almost complete embryo. The isolated animal portion normally forms only ectoderm, although if treated with lithium chloride, which acts as a respiratory inhibitor (Lindahl, 1936), this isolated animal region may form an entire embryo (von Ubisch, 1925). Thus, by inhibiting the high dehydrogenase activity, the substances normally utilized in formation of ectoderm are diverted into endoderm and mesoderm.

This makes the comparison with labile systems almost complete. We have an internal organization which is basically a difference in the colloidal state of the dehydrogenase-substrate system. However, this system is semi-labile, to the extent that lithium chloride can change it. It is more fixed than a labile system, since the organization persists to some extent after the parts are separated. This is not true of the labile system, which becomes completely reorganized after separation by a changed oxygen/metabolite ratio.

What are some of the special characteristics of the semi-labile system? We have seen how lithium chloride acting on the isolated animal portion diverts some of the ectoderm into endoderm. Similarly, lithium chloride acting on the entire egg converts ectoderm into endoderm. On the other hand, potassium thiocyanate, applied before the egg is fertilized, produces embryos composed exclusively of ectoderm thus converting the normal endoderm into ectoderm. In this respect it is interesting to know that lithium and SCN are antagonistic with respect to hydration of proteins. Lithium decreases, while SCN increases hydration. Sulfate ions likewise decrease hydration, and when *absent* from sea water produce the same effect on the development of the egg as the SCN. Other substances altering organization would be expected to affect the colloidal structure of the proteins, for example, KCl and KI. These agents, by altering the activity of the dehydrogenase-substrate complex, could easily change the quantitative relationships between the parts of the egg and so change internal organization. The alteration could simply be an adsorption or elution of catalyst modifiers.

The amphibian organizer phenomena should be included in a discussion of semi-labile systems. For, while the ventral half of the egg (non-organizer) usually forms an unorganized mass of cells and the dorsal half (organizer) develops into a whole embryo, the ventral half may form an embryo if some of the organizer is added. Thus, as in the case of the sea urchin, the differences between the dorsal and ventral halves of the egg must be largely, if not completely, quantitative in nature.

If we limit ourselves to the organization of a neural tube, then certain similarities to previously discussed systems appear. In the first place, the organizing factors

must be relatively simple, for repeated attempts to find the naturally occurring stimulus for neural differentiation have led only to the discovery that several chemically unrelated compounds will stimulate: for example, certain sterols, phospholipids, fatty acids, acid and alkaline buffers, digitonin, crude protein extracts, and others. These diverse compounds must activate some internal organization in the ectoderm somewhat in the manner that agents are able to activate the egg in earlier development, *i.e.*, by modification of the catalysts through adsorption or elution. In normal development the roof of the archenteron supplies the stimulus, but, like the sperm cell in fertilization, the roof of the archenteron is not necessary. Apparently it simply creates a change in the ectoderm, releasing substances already present which form the basic structure of the neural tube.

Secondly, there appears to be some labile internal organization in the presumptive neural plate itself, such that it responds in a definite way to the stimulus of the organizer. Studies in progress are beginning to show that this internal organization is correlated with oxygen consumption. For the rate of oxygen consumption is highest at the animal pole and lowest at the vegetal pole. The presumptive neural plate is arranged with the brain at the animal pole and the spinal cord running vegetally. Thus it is fair to presume that the brain consumes oxygen at a higher rate than the spinal cord. When the stimulus (or organizer) is applied to this presumptive neural plate, the brain and spinal cord develop with respect to this internal organization, which may be based on differences in respiratory activity. This internal organization is semi-labile, as the part which becomes spinal cord will become brain if transplanted to the normal brain region. This is entirely consistent with the characteristics of labile and semi-labile systems.

Stable systems. These are characterized by the difficulty with which normal development can be altered. Cutting these systems and so exposing new surfaces rarely alters the internal organization, as contrasted with labile and semi-labile systems. New arrangements of the stable system likewise show that the parts are relatively unaltered and that the internal organization persists. Chemical treatment has little effect beyond injury.

In these forms it is not possible to decide whether qualitative differences comprise internal organization, so that particular chemical compounds determine the structures which various cells form; or whether the quantitative differences are so rigidly fixed to the structure of the egg that changes in concentration are difficult. In the first case the change of internal organization would be very difficult, since it would involve the synthesis of some new compound. However, if the latter case is true, more hope for changes in internal organization may be offered. For supposing that the actual concentration of enzyme-substrate was different in different parts of the cell, we might still hope to change this organization by means of inhibitors and stimulators of various sorts. These agents would be respiratory poisons and catalysts, or even salt solutions, as in the case of semi-labile systems.

In this connection it should be remembered that no system is absolutely stable, and recent years have modified greatly our concept of some of the classical stable systems. Their cells have been demonstrated to undergo changes in development (Rose, 1939) and in other cases two embryos have been obtained from one egg (Novikoff, 1939). Even the very early workers found that a small portion of the protoplasm of the egg was responsible for a large part of the embryo, indicating organizer phenomena.

The guiding principle throughout this discussion is that internal organization is largely delineated by quantitative differences in the activity of the enzymes of the system. The activity of these enzymes depends upon their colloidal state which is affected by external as well as internal factors. Salts, acids, and bases can bring about physical changes in the enzymes affecting their activities and changing internal organization of the egg. The sea urchin is a well studied example. Respiratory

catalysts and inhibitors increase or decrease the rate of reactions in which these enzymes serve as catalysts, thereby producing effects similar to the catalysts themselves and so changing internal organization.

Two consequences of these differing activities of enzymes are the competition of the parts of a system for substrates and the differential production of metabolites. In some forms it is clear that this competition phenomenon enables the low-metabolizing parts of a system to form certain structures, but not others. This gives rise to organization of the parts of a system into an orderly whole, with the control of organization residing in the part exhibiting the greatest over-all velocity of chemical reactions. For, once such a region is established, the competition phenomena will set up the regions exhibiting lower reaction rates.

The Maintainance of Differentiation

The foregoing has dealt with the initial steps in the process of differentiation and organization. However, the process very early must reach a stage at which it becomes relatively irreversible, *i.e.*, epidermal cells continue to produce epidermal cells even when placed in the environment of other types of cells. To explain this inheritance in the different cell types we must resort to a hypothesis such as that of Alexander and Bridges (1928) and of Alexander, (1931, 1932, 1937, 1939). The reproducible units are considered to be similar to viruses in that they catalyze their own formation. These autocatalytic catalysts are termed *moleculobionts*, and are to be sought for in the proteins of the cell. They vary from one type of cell to another, but arise in some way from the original egg proteins.

A possible mode of origin of these different catalysts from the original catalysts in the egg is by catalyst modification (Alexander, 1931, 1932, 1937, 1939), which may be brought about by a variety of means, *e.g.*, change in chemical structure, adsorption, or elution. In view of the foregoing discussion the following suggestion is made. We begin with a simple difference in the activity of the catalysts in different parts of the egg. This leads to a modification of the chemical milieu of those parts of the egg, caused by (1) changes in the concentration of metabolites brought about by differences in the rate of metabolism, and (2) changes in the concentration of substances which are used in metabolism. These concentration differences alter the catalysts present by selective adsorption of different molecules in various parts of the developing egg. Thus a number of new catalysts arise, which change the structure and activity of the cells, and result in what we call differentiation. Since these are auto-catalytic catalysts, they continue to build up, and daughter cells are formed which are similar to the parent cells.

The indications are that, once the primary cells are modified by selective adsorption, they become rather stable and it is not easy to change the cell type thereafter. However, such a change is simply a chemical problem of how further to modify the catalysts by adsorption of still more new molecules, or by elution of those molecules which have become adsorbed. It is quite possible that cell types can be changed back and forth with ease when the appropriate treatment is found. Our discussion would point to a treatment by substances which cause elution of adsorbed molecules, so that the modified catalyst could return to its original form, which then might be modified in a different way by another milieu.

Rate of Metabolism and Organization

Certain precautions must be taken in interpreting experiments dealing with the relation between the rate of metabolism and organization. In the first place, not all metabolism is concerned with organization. For example, respiration may be changed without affecting organization. Thus there is an active and a resting metabolism with respect to organization. Indications are that the active metabolism in some cases is only a fraction, say 10 per cent, of the total metabolism. In these

cases one must find which part of the total metabolism is concerned with organization. This can be done by applying to the system a wide variety of respiratory substrates, poisons and catalysts, and determining which part of the process is changed simultaneously with the organization.

In the second place, it is not the absolute rate of metabolism which is important, but rather the relative rate, or better the ratio between the rates of the different parts of the system. Thus temperature changes which may double or halve the absolute rate have little (however distinct and significant) effect on the internal organization. This again shows that the significant part of internal organization is the competition (either for substrates or by inhibitory action of metabolites) between regions of varying rates of metabolism. Changes in temperature bring about minor but very significant differences in organization, such as change in the relative size or number of structures.

The Physical States of Protoplasm Compatible with Life

B. J. LUYET

St. Louis University, St. Louis, Missouri

PHYSICAL PRINCIPLES CONCERNING THE VITREOUS STATE, VITRIFICATION AND DEVITRIFICATION

Relation between Velocity of Crystallization and Temperature. Crystallization is one of the many phenomena of nature which are governed by different laws at macroscopic and at molecular levels. The velocity of crystallization of a relatively large quantity of liquid *increases* at decreasing temperatures, while the velocity of growth of individual crystals *decreases* at decreasing temperatures (below the freezing point). The second part of this statement has been established by Tammann,¹ who demonstrated that the relation between the velocity of crystal growth and the temperature at the surface of a growing crystal—as opposed to the temperature in the bulk of the liquid—is of the type represented by the curve CG in Fig. 1. The difference between the macroscopic and the molecular phenomena is due to the fact

that, when crystals begin to form in a liquid, heat is generated and the temperature rises to the melting point, thus causing the growth of crystals to stop. Before a new growth period can start, the heat produced must be eliminated. So the factor which controls the velocity of bulk freezing is not the rapidity of crystal growth, but the rapidity of heat elimination. Consequently, low temperatures accelerate bulk freezing and retard crystal growth.

Relation between the Velocity of Formation of Crystalline Nuclei and Temperature. In the same series of studies, Tammann investigated the rate of formation of crystalline nuclei by counting the number of crystals which appear independently at several points in a supercooled liquid, during a given length of time, at given temperatures. He obtained curves of the type represented in Fig. 1, under NF. In these curves the range of temperatures extending from the freezing point downward consists of three zones: (1) a zone A where the velocity of formation of the nuclei is infinitely small, (2) a zone B where the velocity increases to a maximum and decreases again, (3) a zone C where the velocity once more reaches zero.

Various Types of Solidification. The resultant action of temperature on the two phenomena of crystal formation and crystal growth is as follows:

(a) In the zone A (Fig. 1) where the number of nuclei is low and crystal growth rapid, only a few, but large crystals will result.

FIGURE 1. Graph representing the velocity of crystal growth (curve CG) and of the formation of crystalline nuclei (curve NF) in terms of decreasing temperatures; V, velocity; T, temperature; F. P., freezing point. (Curves drawn from Tammann's¹ data.)

(b) In the zone B, where the number of nuclei is high and growth velocity low, there will be many small crystals.

(c) In the zone C, where no nuclei are formed, and where they could not grow if they were formed, there will evidently be no crystallization. The substance will usually solidify in an amorphous state.

Action of Solutes on the Rate of Crystallization of a Solvent. Callow² reported that 1 per cent gelatin in solution in water reduces the rate of crystallization of the solvent to about one-half its value and that 3 per cent gelatin reduces it 350 times. Tammann and Büchner³ made similar observations on the effect of sodium chloride, sulfuric acid, glycerin, alcohol and sucrose on the velocity of freezing of water. The presence of solutes may thus be of considerable importance in any operation involving the crystallization velocity.

Vitrification. From what has been said it follows that, if a liquid is not permitted to stay in zone B, it will not crystallize. If it can be carried from the zone A to the zone C, across B, so rapidly that the crystalline nuclei have no time to form, it will assume the vitreous state.

One can facilitate the rapid transition across zone B in two ways: (1) by reducing the bulk of the material, thus increasing the rate of cooling, and (2) by adding a solute, thus lowering the crystallization velocity.

In fact one can easily vitrify small amounts of various concentrated aqueous solutions by smearing a drop on a thin, glass or mica support and immersing this

preparation in liquid air (for the details of the procedure, see Luyet ⁴ and Barnes and Matthews ⁵).

The vitrification of pure water requires a much higher cooling velocity, which was obtained in the following manner. Drops of water falling from a pipette were caught between a metal abutter cooled in liquid air and placed beyond the falling drops and a metal projectile also cooled in liquid air and shot against the abutter by the propelling action of the spring of a toy pistol. The drops flattened between the two pieces of metal, solidified into pellicles, a few microns thick, which were opaque when observed between crossed nicols.

Barnes and Matthews ⁵ made an x-ray study of the structure of gelatin gels of 50 to 70 per cent concentrations solidified by the method of vitrification described above and found no trace of crystalline structure. But it is possible that in less concentrated gelatin gels, or in various other gels or solutions, or mostly in pure water as treated in our experiments, minute crystals, either completely formed and ready to grow larger, or in some incipient stage of formation, may be detected by x-ray analysis.

Devitrification (Crystallization at Rising Temperatures). When a substance in the vitreous state is warmed from the zone C to the zone B it "devitrifies," that is, it crystallizes. Barnes and Matthews (*loc. cit.*) obtained the x-ray diffraction pattern of ice when they allowed gelatin gels of 50 to 63 per cent concentration, previously vitrified in liquid air, to warm up "until the temperature was just below the melting point" and then lowered the temperature again to its original value.

We determined the devitrification temperatures of several aqueous solutions. The procedure consisted in vitrifying by immersion in liquid air a drop of the solution to be investigated, placed between two thin glass plates, and observing at gradually rising temperatures when crystallization occurred (that is, when the preparation became opaque). It was found that, in general, the devitrification temperatures rose as the molecular weight of the solutes increased. The values observed for a series of more or less comparable compounds are as follows: formaldehyde: -80.5° , glucose: -40.6° , sucrose: -31.8° , dextrin: -9.4°C . (The reader will have a better idea of the degree of comparability of these results by consulting the original papers in which the effect of concentration is discussed and the duration of devitrification of the same amounts of different solutions is mentioned.)

As to the devitrification temperature of pure water, we have no information except that the pellicles of solid water obtained with the vitrifying gun, when allowed to warm gradually in a liquid bath, while continuously observed between crossed nicols, showed an intense reestablishment of light immediately before melting, that is, in the neighborhood of -1°C . Whether this temperature corresponds to a sudden increase in the crystallization velocity of individual crystals, to the incorporation of small crystals into larger ones, or to the formation of a new phase, we cannot yet say.

Crystallization at rising temperatures can be avoided by a rapid warming, in the same manner as crystallization at decreasing temperatures was avoided by a rapid cooling. Rapid warming is effected by immersion of the vitrified preparations in a warm liquid.

CHANGES OF STATE INVOLVING THE DESTRUCTION OF LIFE

When we use the term *life* in this section we do not mean actual vital activities such as respiration or assimilation, which are inhibited by the low temperature to which we must expose protoplasm to induce the changes of state to be studied. We mean the ability of an organism whose vital functions are inhibited, to resume them when it is brought back to normal temperatures. The problem is whether this ability, and the particular arrangement of the molecules of protoplasm that underlies it, are irreversibly destroyed when some of the molecules are subjected to the rearrangement involved in crystallization, vitrification or devitrification.

Crystallization. It seems quite well established that the *complete* crystallization of the freezable water of an organism in the vegetative state, with *full* water content, causes death. This was observed in most of the researches permitting an accurate determination of the internal temperature of the frozen organism, and of the quantity of ice formed in it. (For details see the review by Luyet and Gehenio,⁶ mostly the sections concerning *Amphibia* and *Fishes*.)

It is also well known that organisms which support dehydration and which, when desiccated, have such a low water content that no ice can be formed in them (seeds, moss, nematodes, rotifers, tardigrades, brine shrimp eggs, etc.) are not injured by the action of low temperatures. The absence of injury where no ice can be formed confirms the view that ice is the injurious factor.

Vitrification. We then undertook to investigate whether the protoplasmic structure would also be destroyed by solidification in the vitreous state. We used for that purpose: (1) monocellular organisms: *Amoebae*, *Myxamoebae*, *Euglenae*, *Paramecia*, *Colpoda*, *spermatozoa*; (2) tissues of higher plants and animals: epidermis of onion, frog muscle fibers; and (3) entire organs or organisms: moss leaves, vinegar eels.

The procedure was as follows: The material was obtained in the smallest possible quantity so that the bulk effect was reduced to the minimum. Its water content was decreased by evaporation or by immersion for a short time in some hypertonic solution. The organisms or organs thus partly dehydrated were placed on thin glass or mica supports and immersed in liquid air. (With monocellular organisms we also used the method of immersing in liquid air films of the culture mounted on a loop of fine wire, or smears, on thin glass supports, of an oil emulsion of the culture, where the organisms were enclosed in droplets of the nutritive medium surrounded by the oil.) After a given length of time the material was withdrawn from liquid air and immersed rapidly in warm water. It was then examined for signs of vitality. The characters considered as criteria of life were *movement* in protozoa, *spermatozoa* and vinegar eels, *plasmolysis* and *deplasmolysis* in plant tissues, and *response to electric stimulation* in muscle fibers.

The amorphous character of the suddenly cooled cells was ascertained in the case of the epidermis of the onion at liquid air temperature, by observation between crossed nicols. As to the other materials we have no direct evidence of their physical state.

The vitality tests gave essentially the following results: (1) Plant epidermal cells maintained their semi-permeability if their water content had been reduced by plasmolysis in a 5 to 15 per cent solution of NaCl before immersion in liquid air. (2) The motility of frog's spermatozoa was partially restored if they had been previously treated with a 40 to 50 per cent solution of sucrose. (3) As many as 79 per cent of the vinegar eels survived the low-temperature treatment when this was preceded by immersion in a 30 per cent solution of ethylene glycol, while only 11 per cent survived without previous dehydration. All the worms were injured. (4) A large proportion of frog's muscle fibers (91 per cent) responded to electric stimulation, though they were considerably injured. (5) The semi-permeable membranes of the cells of moss leaves were in functioning condition, even if exposed to low temperatures with their full water content of 72 per cent. (6) Of the many protozoa treated, only a few myxamoebae survived.

As a rule, when the conditions for vitrification, namely, rapid cooling, rapid re-warming, small mass of material and low water content (the equivalent of the presence of a solute) are satisfied, some revival is possible. And, when none of the organisms treated survives, it is usually observed that one of the precautions for avoiding crystallization has been omitted. The presumption, therefore, is that the dangerous regions in the temperature scale are those at which crystallization occurs. As to the vitreous state, it appears safe for life; but the case of protozoa still remains to be explained.

Devitrification. Vinegar eels, which lend themselves so well to this kind of experiment because of their high degree of motility, were used in an attempt to determine, in a living organism, the range of injurious temperatures of devitrification. After being vitrified in liquid air the worms were transferred into a bath of isopentane, where they were maintained for 1, 5, 15 or 30 minutes at a constant temperature between -50° and 0°C . They were then warmed rapidly and examined. It was found that an exposure of the solidified worms to temperatures from -39° to -5° for 1 minute was always fatal. Exposures to temperatures from -43° to -50° for a period as long as 30 minutes did not prevent revival. When the temperature of exposure passed from -43° to -39° the mortality increased rapidly. These facts fit in well with the idea that in the neighborhood of -43° lies the lower limit of a zone of devitrification temperatures for some essential constituent of the body of these animals.

To summarize, there is a certain amount of evidence that solidification in the amorphous state does not kill protoplasm, but that crystallization, either from the liquid or from the vitreous state, is lethal.

Some Physical Properties of Protoplasm

ROBERT CHAMBERS

Research Professor of Biology, New York University

In our present state of knowledge it is impossible to consider protoplasm otherwise than in living cells. Thus far protoplasm has never been extracted from cells without complete loss of its outstanding property of being alive. Therefore, studies on it must be done within the confines of living cells. This close relationship has caused many to regard a living cell and protoplasm as synonymous on the basis that protoplasm is an organized body of which the structural unit is the living cell. "One of the most striking characteristics of protoplasm is that mechanical crushing destroys it. This holds not only for the integrated cell but also for any viable fragment of protoplasm which may be spontaneously or experimentally separated from the cell. The implication has long been recognized by cytologists that the property of life depends upon a definite architecture of structural nature. Verworn and E. B. Wilson have defined protoplasm as a morphological concept. Hypothetical units of physiological structure have been variously termed micellae by Nägeli, plasomes by Wiesner, bioblasts by O. Hertwig, etc. An attempt to give a chemical significance to the ultimate unit of living matter was made by Pflüger (1875). Pflüger postulated a living protein (*lebendiges Eiweiss*) molecule with a constitution based on a cyanogen radical. Its stability and lability were supposed to depend upon interchanges of atom groups in the molecule, induced by the consumption of oxygen and the liberation of carbonic acid. "Much earlier than Pflüger is the almost forgotten account of Fletcher of the University of Edinburgh in 1835. In his 'Rudiments of Physiology' Fletcher attacked the old hypothesis of a vital spirit. As an alternative he suggested that the elements composing living matter are in a peculiar state of combination. The newer developments in the extraction of proteins, *e.g.*, by ultracentrifuging at very low temperatures, have made possible the isolation of certain viruses hitherto unobtainable by the usual chemical means. This may be a first step toward isolating the extremely unstable complex which at present can be termed only as protoplasmic protein.*

This paper deals entirely with some of the properties of protoplasm as they are found in the living cell. Hitherto, in most studies of this nature not involving the technique of micromanipulation, it has been customary to deal with the cell in its entirety or with masses of cells. The fact must be appreciated that a cell includes more than its protoplasm. Botanists have been much more aware of this than have animal cytologists largely because of the prominence in the plant cell of its extraneous coats. Hence, the use of the botanical term *protoplast* to indicate the more truly protoplasmic body lying within the cellulose and pectinaceous walls of the cell. Among animal cells the extraneous coats are far less evident and, generally, have not been taken into serious consideration. This has given rise to certain misconceptions regarding, for example, the antagonistic action of salts. Actually, the mutual antagonism of NaCl and CaCl₂ refers more particularly to the action of these two salts on the extraneous material which surrounds cells and which serves to bind them to-

* Chambers, R., "The Micromanipulation of Living Cells. The Cell and Protoplasm," Publ. 14, Am. Assn. Adv. Sci., The Science Press, Washington, D. C., pp. 28-29, 1940.

gether. When the extraneous coats are removed it has been found that the maintenance of the actual protoplasmic surface film or layer depends on the simultaneous presence of NaCl and KCl in definite, proportional concentrations irrespective of the presence of CaCl_2 .

For this reason the subject matter of this paper first deals with the nature of the extraneous coats. Then it deals with the protoplasmic surface layer and finally with certain properties of the protoplasm within its surface layer or plasma membrane. The use of the term *plasma membrane* is of historic interest since it was first used to denote that part of a living cell upon which the viability of its internal protoplasm depends. In regard to the morphology of protoplasm it has been impossible, thus far, to consider the internal protoplasm without the presence of its investing plasma membrane or protoplasmic surface layer. The disintegration of the one has always accompanied the disintegration of the other. Can it be that the stability of the protein-like complex of protoplasm depends upon the presence of a plasma membrane the selective permeability of which preserves the proper environment within the cell?

Extraneous Coats of Living Cells

All living cells, without exception, at sometime have membranes or jelly-like coatings. These extraneous coats may be delicate or tough, thin or thick, soft or hard, elastic or rigid, viscous or plastic, proteinaceous or pectinaceous. All coatings originate from the living cell. The important feature about extraneous coats is that each layer may be removed mechanically or by suitable chemical solvents so that only a final limiting surface remains. The remaining surface is the protoplasmic surface layer, a structure which cannot be mistreated without seriously damaging the cell, or removed without completely destroying the cell. In the absence of injury, cells which have been denuded of their extraneous coats remain viable.

Nearly all investigations dealing with surface phenomena of living cells have been made on cells which possessed some or all of their normal complement of extraneous coats. Only during recent years have serious attempts been made to investigate cells from which all extraneous coats were removed. The physical properties of the extraneous coats have been recently reviewed.¹⁵

The eggs of various Echinoderms, particularly those from sea-urchins, have provided useful material for the study of a variety of extraneous coats. Mature, unfertilized sea-urchin eggs possess two well-defined extraneous coats. The protoplasmic surface layer is bounded by a thin, delicate vitelline membrane. Outside the vitelline membrane is a soft, invisible layer of jelly.

On insemination, the vitelline membrane separates from the protoplasmic surface layer, elevates and becomes the fertilization membrane.* The latter, when fully developed, differs conspicuously from its precursors and possesses the greatest amount of mechanical strength and resistance to chemical action of all membranes one encounters on sea-urchin eggs. Several minutes after insemination, the hyaline layer is secreted by the zygote and this layer accumulates on the surface previously occupied by the vitelline membrane.

The jelly layer may be readily removed by repeated washing of the sea-urchin eggs in isosmotic NaCl solutions slightly diluted with sea-water. Mature sea-urchin eggs, with the jelly removed will, on insemination, develop fertilization membranes and cleave as well as untreated eggs. The jelly layer is a dispensable coat.

The vitelline membrane may be removed in several ways. The most commonly used method is to inseminate the eggs and then transfer such eggs to isosmotic KCl solutions within 1.5 minutes after insemination. The incipient fertilization membrane which originates from the vitelline membrane is dispersible in the presence of KCl. If such eggs are returned to sea-water, the development is apparently normal, except that no fertilization membrane is present.

* See article by E. E. Just in Vol. II of this series. J.A.

The tangential rigidity of the extraneous coats can be compared by employing the oil-coalescence method.¹⁵ Under certain conditions, sea-urchin eggs will coalesce with oil drops applied to their surface. One of the conditions which determines the ease with which coalescence occurs is the mechanical resistance offered by an extraneous coat. The completely denuded egg shows the highest tendency to coalesce with oil drops.

Mature, unfertilized sea-urchin eggs when immersed in isosmotic KCl solutions show the same tendency to coalesce with oil drops as exhibited by similar eggs immersed in sea-water. One interprets this reaction to signify that KCl has no action on the vitelline membrane. On the other hand, unfertilized eggs immersed in isosmotic CaCl_2 solutions have a coalescence about 8 to 10 times higher than control eggs immersed either in sea-water or in isosmotic KCl solutions. Excess calcium ions tend to increase either the liquidity or brittleness of the vitelline membrane, either of which would decrease the effectiveness of the vitelline membrane as a physical barrier to coalescence. Calcium also appears to increase the adhesiveness of the vitelline membrane. An oil drop brought into contact with an unfertilized egg (jelly removed) immersed in Ca solutions and suddenly pulled away, will carry with it a small portion of the egg. This adhesiveness undoubtedly enhances the contact between the egg and oil drop, thereby increasing still further the tendency of such eggs to coalesce with oil drops.

Because of its remarkable rigidity, the fertilization membrane completely prevents coalescence. The fully formed hyaline layer likewise prevents coalescence. It can be mechanically removed with microneedles or by agitating the eggs shortly after it has formed when the membrane breaks and the eggs slip out.

A few minutes after fertilization there develops a hyaline layer several micra in thickness closely investing the surface of the egg cell. One of the outstanding properties of the hyaline layer is its instability in Ca-free media. Fertilized eggs immersed in isosmotic KCl solutions gradually lose their hyaline layers, so that after a period of 15 to 30 minutes in the Ca-free medium, the hyaline layer becomes completely dispersed. Such eggs, providing the fertilization membrane was previously removed, very readily coalesce with oil drops.

The coalescence data, as well as other observations, lead to the conclusions that sea-urchin eggs with fertilization membranes removed mechanically (by shaking) and kept in KCl solutions for at least 30 minutes have the minimum of extraneous coatings. Such cells may be considered as being essentially free of their extraneous coats. The weakness of cells treated in this way to mechanical stress and interfacial forces suggests that the external surface on these cells is actually the protoplasmic surface layer.

All extraneous coatings including jelly, vitelline and fertilization membranes, and hyaline layers are non-essential to the life of the cell. The absence of any of these coatings does not prevent a fertilized egg from cleaving. Eggs from which vitelline membranes have been removed by chemical means are capable of being inseminated and will cleave normally. The hyaline layer is a dispensable coat of the single cell. However, if it is removed from the cleaving egg, the blastomeres will not remain attached except by temporary connecting stalks. The hyaline layer is therefore essential to a multicellular organism, and must be considered as a primitive intercellular cement.

A substance released by sea-urchin blastulae at the time of hatching dissolves fertilization membranes.¹⁶ This substance is, at present, considered as an enzyme, and it can be recovered and preserved in sea-water. The action of this substance is most rapid on the transitional membrane (intermediate stage between the vitelline membrane and the tough fertilization membrane). The enzyme, however, has no effect on the precursor of the fertilization membrane (the vitelline membrane), nor on the hyaline layer.

Experimental evidence has been recently presented⁵ which indicates that the normal growth in dimensions of the fertilization membrane is independent of elastic stretching such as might be occasioned by osmotic phenomena. On activation by sperm insemination, the vitelline membrane begins to lift away from the protoplasmic surface layer, and expands until it lies an appreciable distance away from the egg's surface. The expansibility has been shown to be independent of the content of the perivitelline space which the developing fertilization membrane creates. It is entirely possible that the intrinsic expansibility of the membrane-forming substance is due to the change in configuration of the protein molecules which make up a significant fraction of the fertilization membrane.

The Protoplasmic Surface Layer

Pfeffer was the first to use the term *plasma membrane* for the protoplasmic surface layer. He postulated the existence of a semi-permeable membrane to account for the results obtained in his classic studies on the osmotic properties of plant cells. Pfeffer and Nageli, who preceded him, regarded the surface of protoplasm as a hap-togen membrane, protein in nature.

Butschli was opposed to the idea of a differentiated plasma membrane, holding that the integrity of a protoplasmic body is due to the immiscibility of its material with the aqueous environment. The absorption of water by protoplasm he regarded as analogous to the way in which the water fluids diffuse into fatty oils where they may collect as aqueous drops. Lepeschkin¹⁹ has accumulated considerable data on this point, one of his chief arguments for Butschli's view being that protoplasm can absorb water only to a limited degree. This he showed by exposing the protoplasm of marine foraminifera and of certain algae to diluted sea-water and noting that the protoplasm of the cells, after swelling to a limited degree, became filled with vacuoles, the size and number of which varied with the dilution of the medium. When the cells were returned to ordinary sea-water the vacuoles disappeared and the cells regained their normal appearance.

It is true that the penetrability into living cells of many substances, particularly those which are lipid-soluble, can be explained without postulating that a selective permeability is limited to a peripheral layer of the protoplasm. On the other hand, the membrane theory explains many more phenomena.

Experimental work employing the oil-coalescence method has shown that the protoplasmic surface layer is essential to the life of the cell. So far no method has been worked out which permits the removal of this layer without causing irreversible damage to the cell. In the absence of extraneous coats the protoplasmic surface layer is very delicate. Very slight mechanical stresses cause an irreparable rupture, as evidenced by the tearing of fertilized eggs developing in Ca-free media. Coalescence of such cells with oil drops as small as 5 microns in diameter sets off an immediate disintegration of the entire cell. Unfertilized *Arbacia* eggs with vitelline membranes intact withstand considerable mechanical strain, and coalescence with oil drops as large as 50 microns in diameter does not destroy the cell.¹⁵

Experiments on the electrical conductivity of cells offer another argument in favor of the idea that the external surface layer of protoplasm possesses properties decidedly different from those of the interior. These experiments were first done by Hoeber¹³ on red blood-cells in serum and on frog's muscle in isotonic NaCl. Hoeber found that the impedance to the passage of a current decreases with a rise in the frequency of the alternating current and that at very high frequencies the impedance falls to a low value.

The more recent work of Cole and his collaborators⁹ has shown that the cell membrane has a resistance of the order of 1000 ohms/cm². This is substantially a measure of the ability of the cell surface to transmit ions. The cell surface likewise possesses a capacitance of about 1 microfarad/cm². The latter represents the ion-

impermeable structure. Cole⁹ concludes: "The mechanism of the ion permeability is not obvious from resistance measurements but the capacity and dielectric loss suggest that the impermeable structure may be highly organized and a number of molecules in thickness."

Other important measurements on the physical properties of protoplasmic surface layers have been made by Harvey and his collaborators. These deal with measurements on the tension at the surface of living cells, a subject recently reviewed by Harvey¹⁰ and by Harvey and Danielli.¹¹ The tension is of a low order of magnitude, and the values suggest that the protoplasmic surface layer is polymolecular, consisting of layers of protein molecules alternating with layers of aliphatic compounds, a concept also supported by the optical data of Schmitt, Bear, and Ponder.²¹

The relative impermeability of the surface of protoplasm as contrasted with its interior has also been shown by the microinjection of various substances. Fresh-water amebas, immersed in solutions of magnesium chloride at concentrations as high as 1 to 2 molar, move about freely and show no injury. On the other hand, an injection of 0.2M $MgCl_2$ of an amount less than the volume of the nucleus of the ameba causes, at the site of the injection, an immediate coagulation which spreads until the entire ameba is involved. The effect of $CaCl_2$ is similar to that of $MgCl_2$ except for the complication that the ameba immediately reacts by pinching off the region at the site of injection before the salt has had time to spread. The question of old and newly formed surfaces is discussed elsewhere.

The diffusibility through the interior of protoplasm is most strikingly seen when injections are made of aqueous solutions of dyes which do not penetrate the cell from the medium. This is illustrated by injecting an aqueous solution of a non-toxic acid dye, such as chlorphenol red into a variety of cells such as living muscle fibers, gastric mucosa cells, starfish eggs and fresh water amebas. If a microdroplet of the solution is injected into the cytoplasm, the color quickly diffuses until it stops at the surface boundary. Evidently, the interior of the cytoplasm is freely permeable to the dye and the inability of the dye to get in from without or to pass out from within must be ascribed to the existence of a surface film or layer which is impermeable to the dye from either side. A great number of aqueous solutions have been injected into a variety of cells and, in every instance, the solutions, provided they are non-toxic and are of the type which do not penetrate from without, will diffuse through the interior when injected.

Interesting cases are the injection of $NaHCO_3$ and of NH_4Cl into the cytoplasm of a starfish egg. It has been known that CO_2 and NH_3 readily penetrate living cells whereas the highly dissociated $NaCl$ and $NaOH$ do not. Jacobs¹⁴ had shown that starfish eggs, immersed in an alkaline solution of $NaHCO_3$, develop an intracellular acidity while, on the other hand, an intracellular alkalinity occurs when the eggs are exposed to a solution of ammonium chloride. However, when these solutions are injected directly into the eggs the results are reversed. This is because the injection brings the entire solution into the interior of the cell, with the result that the internal protoplasm reacts to the alkalinity of the carbonate and to the acidity of the ammonium chloride solutions.

The very fluid state of the plasma membrane can be demonstrated in the following manner with a starfish egg. The extraneous coating of an egg is torn and a part of the protoplasm allowed to flow out as an exovate. With a delicate microneedle the naked surface of the exovate is seized and dragged out for some distance in the form of a filament. On reversing the movement of the needle the substance of the filament flows back into the exovate with no sign of wrinkling on its surface. If the filament is stretched farther it may break into a string of coherent droplets. On lessening the tension the droplets flow together and when the filament is released it flows back into the main body of the protoplasm.

Another indication of the fluidity of the protoplasmic surface is the churning movements which can be induced in an unfertilized, mature *Arbacia* egg denuded of its extraneous coatings. It is significant that this experiment can be done with eggs immersed either in sea-water, in solutions of calcium or of potassium chloride. Eggs previously stratified by centrifugation exhibit the same property. The eggs were mounted in a broad, shallow hanging drop and those adhering to the coverslip pushed gently with a blunt microneedle. As the egg was pushed along the undersurface of a coverslip, peripheral currents appeared, streaming forward along the two sides and backward along the top and bottom of the egg. Extraneous particles adhering to the surface clearly showed by their movement that the streaming involved the surface. A drop of olive oil, applied to the surface which it caps, was carried forward along the side and backward along the undersurface of the egg.

A striking result occurred when the oil-cap was large enough to be so maneuvered, during the pushing of the egg, that it lay over the region including the two opposing, peripheral currents. When the currents once got under way the oil-cap broke in two, each portion being carried along in an opposite direction.

Still another experiment was the following: A drop of oil, exuding from the micropipette but remaining continuous with the oil in the pipette, was brought into contact with the surface which it capped. By moving the pipette the oil slipped over the surface but could not be pulled off without carrying some protoplasm away with it. The cap of oil on the protoplasmic surface behaved like a drop of oil on the surface of water.²

Thickness of the Protoplasmic Surface Layer

Under dark-field illumination a bright line frequently is visible at the boundary of the protoplasm and some investigators have ascribed a measureable thickness to it. However, it is highly probable that such measurements include more than the protoplasmic surface layer *per se*. In the case of unfertilized sea-urchin eggs, it would be difficult indeed to distinguish between the limits of the vitelline membrane and of the protoplasmic surface layer.

Injection experiments indicate that the thickness of the protoplasmic surface layer is far too small to be microscopically visible. If, for example, an ameba or a starfish egg is immersed in a solution of a dye which cannot penetrate and if a quantity of the same solution is injected into the cell there is no evidence of a colorless zone between the color inside and outside the cell.

Measurements have been made of the thickness of the bright line which is to be seen bounding the surface of isolated cells under darkfield illumination. Such lines are very noticeable and seem to have an appreciable thickness, for example, around fibroblasts and other cells in tissue culture. The phenomenon of apparent thickness of the line is probably an optical illusion, especially since the visibility of this line is due to the effect of light scattering. When two or more such cells are in intimate contact the bounding line between them disappears completely. Indeed, a sheet of cohering cells viewed in the dark field gives the effect of a syncytium with a boundary line appearing only along the free margin of the sheet.⁶

The recent electrical measurements by Cole⁹ indicate that the protoplasmic surface layer may be a membrane at least 100 Å thick (exact estimations of membrane thickness from capacitance data are impossible due to uncertain values for the dielectric constant of the membrane components). The optical data of Waugh and Schmitt²² likewise suggest that the protoplasmic surface layer is polymolecular.

The Protoplasmic Surface Layer in Relation to Extraneous Coats

All extraneous coatings are those which normally envelop cells but are not essential for their life. On the other hand, without the protoplasmic surface layer

the cell cannot survive. This layer is extremely delicate and easily ruptured. The rupture, unless immediately repaired, is inevitably followed by cytolysis. This bounding layer must therefore be regarded as an integral and indispensable part of the protoplasm. In nature it is probably seldom, if ever, exposed, being protected by an extraneous coat which, in the fertilized Echinoderm egg, is the hyaline layer. Three separate techniques have been employed to expose the actual protoplasmic surface layer of the *Arbacia* egg: the mechanical, for coatings which are sufficiently brittle and loosely stretched so as to be removable by shaking; the chemical, effective in removing the intercellular cement and hyaline layer material which are dispersible in the presence of excess monovalent cations; and the biological, in which, for example, the act of fertilizing an egg induces the lifting of the vitelline membrane which can then be removed by shaking. A combination of the three techniques is sometimes necessary to ensure the exposure of the protoplasmic surface.¹⁵ So far, the medium best tolerated by naked *Arbacia* eggs is a mixture of NaCl and KCl in proportions of 19:1 in concentrations isotonic with sea-water but at a pH more acid than that of sea-water, i.e., 7.0. In these solutions the naked eggs continue to cleave at the normal rate for many generations, the resulting blastomeres falling apart and continuing to exist as isolated cells. This demonstrates the dispensibility of calcium in the surrounding medium as a factor not only in the maintenance, but also in the re-formation of the protoplasmic surface layer, since the development of thousands of cells from the original ovum must involve an enormous increase in total surface area.

There is a significant difference in the way the protoplasmic surface is re-formed in the presence and in the absence of calcium. In the latter case, no repair is possible if the surface layer is actually torn to expose the internal cytoplasm. No interface develops; the cytoplasm flows out and a disintegration of the surface layer spreads from the margin of the tear over the rest of the cell. However, as long as no actual tear occurs, the protoplasmic body can be pinched with microneedles into several rounded bodies of viable protoplasm and strands can be drawn out which may separate from the main body with no evidence of cytolysis. The isolated pieces immediately round up into spheres as long as no extraneous material is present to restrain them. The resulting increase in area of the protoplasmic surface layer is to be accounted for not only by the stretching of a pre-existing layer but also by the addition of surface layer material from the underlying cytoplasm. This type of surface formation also seems to be the only means in media containing a disproportionately large amount of calcium in which an actual rupture, occasioned by a mere scratch of the surface, results in an irreversible coagulation of the entire protoplasm.³

Attempts have been made to apply a solution of calcium chloride to the inner surface of the plasma membrane of the sea-urchin egg. A micropipette is inserted through the interior and the solution expelled when the tip of the pipette is close to the inner side of the far surface. The result is always a coagulation; friable strips can then be pulled from the surface with a needle. However, it is impossible to ascertain whether the injected CaCl_2 coagulates the plasma membrane by attacking it from the inside, or whether the coagulation is due to the action on the cytoplasmic material underlying it.

Repair of the Protoplasmic Surface Film and its Permeability

The protoplasm of a living cell is able to repair a torn surface if the tear is not too extensive, and if the environment is normal. This is well illustrated in microdissection experiments on starfish eggs in sea-water. No breakdown occurs if the tip of the needle is moved slowly through the protoplasm and out of its surface. But if the piercing action is performed suddenly, the surface film disrupts and the exposed cytoplasm will begin to pour out and its granules to scatter in the medium. While this is occurring, films may appear around the masses of the disorganizing material which swell and burst. Frequently films form within what appears to be normal cy-

toplasm. These films may unite and reach the intact film which surrounds the remaining portion of the egg after which no further disintegration occurs.

It is difficult to decide between the relative permeability of old and freshly formed surface films of protoplasm. When sea-urchin egg, with a freshly formed surface film where it had previously been torn with microneedles, is immersed in hypotonic sea-water the portion covered by the new film bulges outward. However, this indicates that the new film is simply weaker owing to the lack in that region of a restraining, incipient vitelline membrane and to the absence of an underlying, gelated cortex. No such bulge appears when the egg is in the normal sea-water, unless mechanical pressure is brought to bear on the egg. Numerous attempts have been made to observe the penetration of normally non-penetrating dyes across the newly formed film. None have been successful. It would appear that the new film, when once formed completely, is no more permeable than the pre-existing film surrounding a normal egg.

The Nuclear Membrane

The nucleus is surrounded by a morphologically constituted membrane which can be torn. Its repair has never been observed and the tear always results in cytolysis. It is possible to puncture the nucleus and to inject dyes into it. However, subsequent removal of the micropipette is generally unsuccessful unless done with extreme care.

Its permeability is of a different order from that of the plasma membrane. In this regard, an interesting feature is the fact that all cell non-penetrating acid dyes which have been injected into the cytoplasm or the nucleus can diffuse across the nuclear membrane. The dyes eventually accumulate either in the nucleus or the cytoplasm, according to whether the pH of the nucleus or the cytoplasm respectively is the pH of a medium for which the dye has a preference.

The Consistency of Protoplasm

The physiologically active protoplasmic surface layer is to be regarded as an exceedingly thin film which determines the selective permeability of the cell and which reacts differently to the various salts in the medium. We have already seen that this membrane generally is covered on the outside by a layer. This layer differs in its properties from those of the plasma membrane and can be removed without injury to the protoplast.

The consistency of the internal cytoplasm varies considerably. In many plant protoplasts its fluidity is evident from the continuous streaming movements which it exhibits in cyclosis. In animal cells it is viscid and semi-solid in some cases and liquid in others. In many fluid protoplasts, plant and animal, there is often a more solid cytoplasmic cortex of varying thickness lying directly beneath the plasma membrane.

These differences in consistency have been ascertained by various methods, one of which is to observe the effect of centrifugal force in dislocating the visible constituents within the cell. This method has shown that the viscosity of protoplasm even in the same cell is not constant, and also that variations in the temperature of the environment affect it. Heilbrunn¹² has found, for example, that the internal viscosity of the egg of the clam *Cumingia* is at a maximum at about 15°. On each side of this temperature the viscosity drops to a minimum at about 2° and at 30°. At 1° and at 31° there is a sudden and pronounced increase in the viscosity. He states that this increase in viscosity differs from the heat coagulation of proteins in being reversible. It is possible that the changes in viscosity are related to changes in the permeability of the cell to water at the various temperatures and to changes in the state of the fatty materials within the cell.

The existence of Brownian movement, made visible with dark ground illumina-

tion, appears to be almost a universal phenomenon in protoplasm. This movement can be observed not only in the more fluid regions of cells but also in regions which, by means of microdissecting needles, have been shown to be in a jellied state.

A remarkable feature is the fact that semi-solid regions in protoplasm can sometimes be made suddenly fluid by mechanical agitation. This phenomenon* can be exhibited in a sea-urchin egg undergoing division. At this time the fluid protoplasm is being converted into two jelly-like, semi-solid masses. If a microneedle is inserted into one of the masses and the needle is suddenly jerked, the mass becomes converted immediately into a fluid. If the needle is then removed or allowed to remain stationary for a few minutes the original jellied condition returns and the division of the egg proceeds normally.

It is noteworthy that the normal activities of a cell may continue even when the fluidity of its protoplasm is increased by exposing the cell to hypotonic conditions. This can be seen in fertilized sea-urchin eggs immersed in sea-water diluted with distilled water to as much as two-thirds of its original concentration. Under such conditions the protoplasm becomes so fluid that the visible granules within it undergo such violent oscillatory movement as to be evident even under ordinary transmitted illumination. In spite of this, nuclear division takes place and the egg segments in the usual way but at a slower rate.

The Water-miscibility of Protoplasm

Microinjection experiments present strong evidence that water forms a continuous phase in protoplasm. Aqueous solutions diffuse readily through the cytoplasm of such diverse types of cells as protoplasts of root hair cells, amebas, various ova, muscle fibers, nerve cells, and ciliated epithelial cells. To ensure success the injection must be performed gradually; otherwise a localized disintegration may occur. In the latter case the resulting injury may spread and involve complete cytolysis of the cell. Frequently, however, a membrane may form around the deintegrating region to constitute a vacuole while the rest of the protoplasm remains unaffected.

Water-immiscible fluids, when injected, always form discrete droplets, the shapes of which are conditioned by the presence or absence of structural elements in the cytoplasm. Oil drops often show a tendency to maintain a spherical configuration due to the positive nature of the tension between the oil and the protoplasmic phase.¹⁷ In the muscle fiber of the frog, large oil drops are compressed to cylindrical shapes because of the steric hindrance offered by the shape of the muscle fiber.

The water within the cytoplasm freezes readily.⁷ To demonstrate this, the interior of the sub-cooled cell must be inoculated with an ice-crystal, since the external membrane tends to obstruct the spread of freezing from outside the cell. In the ameba the freezing is in the form of feathery ice-crystals which spread in different directions from the site of the inoculation. In the case of the muscle fiber of a frog the ice forms long, slender columns between denser, longitudinally arranged constituents of the fiber. If the frozen condition is maintained for more than a few minutes the columns progressively enlarge and the dehydration of the protoplasm becomes irreversible. In the case of the ameba the feathery crystals eventually condense into blocks of ice.

Ice crystals, as they are forming, tend to grow along lines of least resistance. In the protoplasm their growing tips have never been seen to puncture relatively stiff structures or pronounced interfacial films. For example, in the ameba, when the feathery crystals reach a gastric vacuole or the contractile vacuole, the tips of the crystals spread over the vacuolar membrane and eventually surround the vacuoles. This fact opens up a field for investigating intra-protoplasmic structures.

* Termed *thixotropy* ("change by touching") by H. Freundlich, who demonstrated it with bentonite and other sols. J. A.

The Protein Phase of Protoplasm

Recent studies based on the interaction between oil drops and protoplasm indicate that proteins and protein complexes are bound together to form a continuous protein phase.¹⁷ The surface-chemical properties of cytoplasmic proteins are considered in another paper in this volume.¹⁸

Evidence based on the diffusibility of water-soluble components as well as on surface-chemical properties of the cytoplasmic proteins suggests that at least two phases are continuous in protoplasm, *i.e.*, the aqueous and the protein.

The Hydrogen-ion Concentration of Protoplasm

Since protoplasm is an organized structure which is destroyed by crushing, it is obvious that a determination of the hydrogen-ion concentration of extracts of crushed tissue cannot be a reliable clue to the intensity of acidity within the dividing cell. Moreover, the unavoidable admixture of intercellular fluid from the tissue introduces an additional source of error.

Reliable results can be obtained only while the protoplasm is living. Electrometric measurements with microelectrodes inserted into living cells have not yet been successful, principally because of the difficulty of ensuring that the tip of the electrode is actually within the cell interior. The tendency of the protoplasmic film is to spread and close a gap. When a needle is inserted into a cell and left there for an appreciable time, the protoplasmic film spreads along the inserted part of the needle to its very tip. The result of this is that the needle comes to lie in a deep depression in the cell with no part of it within the cell. Colorimetric methods, which have afforded fairly consistent results, fall into three groups: the use of natural indicators already existing in cells, vital staining with dyes having a pH virage, and the micro-injection of indicators into the protoplasm. It should be noted here that the pH values obtained are of the aqueous phase of protoplasm. The only indicators to be relied on are those which are more purely water-soluble.

Natural indicators have been unreliable mainly because they are usually localized in vacuoles which do not necessarily have the same pH as the surrounding cytoplasm. This accounts for the findings by botanists of so-called "acid," "neutral" and "basic" cells. The differences are due not to cytoplasm but to the varying pH conditions of their contained vacuoles. An interesting case in this connection is the occasional finding of "blue nuclei" in the petals of purple tulip petals. This condition has been found to be due to injury in which the pigment of the cell vacuole has escaped by rupture of the vacuole followed by the coloration of the alkaline nucleus in the cytolized debris of the cytoplasm.⁴

Vital staining is also unreliable not only because the dyes which penetrate cells from without tend to become segregated in vacuoles but also because of the extreme difficulty of controlling the amount which penetrates. Moreover penetrating dyes are mostly basic in nature and many tend to color fatty bodies in the cell.

The above statements indicate the ease with which errors are likely to be made in determining the pH of living cells.

The micro-injection of lipid-insoluble indicators into the protoplasm has given results least open to question.¹ Even then the color tends to be more or less rapidly segregated in vacuoles. Values obtained for the inter-cytoplasmic pH by the best available methods lie between 6.8 and 7.2. These values have been obtained by injecting a series of indicators of overlapping ranges into such cells as echinoderm eggs, various somatic cells of Vertebrates, the protoplasts of plant cells and amebas. By this method it has also been found that cytoplasmic vacuoles give color indications which have no necessary relation to the observed pH of the surrounding cytoplasm. In Metazoa the cell nucleus has been found to be consistently more alkaline

than cytoplasm, the colorimetric value from injected indicators being in the neighborhood of pH 7.6 to 7.8.

Both cytoplasm and nucleus maintain their respective pH values even when the pH of the environment is shifted by means of penetrating acids and bases. The pH of the cytoplasmic vacuoles, however, changes readily. It was by the color change of neutral red in these vacuoles that the penetration of ammonia and of carbon dioxide was first determined. The buffering power of the protoplasm seems to be limited, and in some cells the pH can be upset to the extent of several tenths of a pH unit on either side of the normal pH value. Death ensues, however, when the pH is thrown too far in either direction, particularly to the acid side. Mechanical injury which initiates cytolysis, even when localized, is accompanied by the production of acidity, the intensity of which is in the neighborhood of pH 5.0 to 5.5. On the other hand the nucleus, when injured, gives no evidence of changed pH.

In short, we find within the living cell the remarkable phenomenon of regions which are circumscribed by well defined membranes and differ in the intensity of their acidity; the nucleus with a pH of 7.6 to 7.8, the cytoplasm with a pH of 6.8 to 7.2, and the cytoplasmic vacuoles with a variable pH which can be shifted readily by penetrating acids and alkalis in the medium.

The Action of Salts on the Internal Protoplasm

The relatively neutral reaction of the internal protoplasm suggests that much of the protein present is on the alkaline side of the isoelectric point. This is borne out by the ease with which coagulation occurs when salts of polyvalent cations, even in very dilute concentrations, are injected into such cells as echinoderm eggs, amebas, and the protoplasts of plant cells. For example, CaCl_2 , in all concentrations down to $M/200$ and MgCl_2 down to $M/1000$ produce a coagulating effect which is either restricted or extensive, according to the amount injected. The injection of NaCl and of KCl ⁸ has no such effect, presumably because they form soluble salts of the protein present.

An additional argument for the existence of proteins on the alkaline side of their isoelectric point in the protoplasm is offered by the fact that picric acid, when injected into a cell, exerts no coagulating reaction. Pollack²⁰ found that it was possible to inject an aqueous solution of picric acid into an ameba with no other effect than to color it a vivid yellow. An explanation for this unexpected result is brought out by injecting a mixture of picric acid with a solution of bromocresol purple, an indicator which is yellow in acid solutions below pH 6.0 and purple in more alkaline solutions. When a moderate amount of the bright-yellow mixture is injected, the ameba assumes a murky green color and remains alive. When too much is injected the color remains yellow and the ameba becomes coagulated and dies. These facts are explained on the basis that with moderate injections the proteins remain on the alkaline side of their isoelectric points and the picric acid is converted into ineffective sodium picrate. However, if the amount injected is large, the excess acid carries the proteins to the acid side of their isoelectric points, thus permitting the formation of an insoluble protein picrate.

The ease with which the internal protoplasm is coagulated by CaCl_2 in contrast to the non-coagulating effect of NaCl and of KCl has been questioned by Heilbrunn,¹² who obtained opposite results by immersing sea-urchin eggs in solutions of NaCl and of CaCl_2 isotonic with sea-water. Physical changes observed within a cell from immersion experiments are difficult to interpret, since they may not always be due to penetration of substances from the medium. However, even if the effect is assumed to be due to penetration the difference in results still may be accounted for by the difference in the amounts of the salts which are brought into the cell by the two methods of experimentation. The difference in the effect of injection and of immersion is brought out strikingly if, instead of CaCl_2 , we use the salt of a basic dye, *e.g.*, neutral

red. This dye is a vital stain and, if present in the medium in appropriate dilutions, will readily penetrate cells and color their cytoplasmic granules and vacuoles without any sign of injuring the cell. However, if an aqueous solution of the dye is injected directly into a cell, the protoplasm at the site of injection is converted immediately into a red, coagulated mass. Apparently, in the usual method of vital staining the dye is taken up by vacuoles and granules as fast as it penetrates and before it has time to combine with the cytoplasmic proteins although coagulation may even then occur if an excessive amount of the dye salt is present in the medium.

Some Surface-chemical Properties of Protoplasmic Proteins *

M. J. KOPAC

Visiting Assistant Professor of Biology, Washington Square College of Arts and Science, New York University, New York, N. Y.

Because of the difficulties involved in the study of protoplasmic proteins it has been necessary to develop new techniques in order to evaluate the properties of such proteins either in living cells or from the residue of freshly disintegrated protoplasm. These new methods are based on the theoretical and experimental procedures of surface chemistry as adapted to microscopic dimensions.

A new interfacial micro-tensiometer has been built which permits the simultaneous measurement of interfacial tension and amounts of proteins or other substances adsorbed at oil-water interfaces.¹⁷ Flow-pressures as well as equilibrium pressures can be measured so that interfacial tensions may be determined at any time after the interface is established.

The adsorption of proteins or other substances at oil-water interfaces is measured by a semi-automatic drop-retraction method. The apparatus permits of precise control over the size of an oil drop poised on the tip of a micropipette. The surface area of an oil drop can be diminished by decreasing its size with the drop-retraction apparatus. The glass wall of the orifice of the micropipette serves as a sweep and, if the retraction is done slowly, proteins will not enter the pipette with the oil. This is

* These investigations were made possible by a grant from the Rockefeller Foundation.

analogous to the compression of surface-adsorbed molecules by the sweep of a straight-edge barrier at the surface of a conventional Langmuir film trough.

Tension measurements at oil-protoplasm interfaces give indications of certain protein characteristics, but these data alone are insufficient to indicate any particular organization in the living cell. Differences in tension lowering, for example, as produced on various oil surfaces by the same protein species cannot be interpreted properly unless one also knows how much protein was adsorbed. Accordingly, interfacial tension measurements must be augmented with measurements on the number of protein molecules adsorbed at oil-water interfaces together with the determination of factors which can modify such adsorption.

The results obtained by applying surface-chemical methods to living cells are summarized in the following sections: (1) Surface activity of intact cytoplasm at oil-water interfaces; (2) surface activity of the residue from rapidly disintegrated *Arbacia* egg cytoplasm; (3) protein adsorption at oil-water interfaces; and (4) spontaneous Devaux effect at oil-protoplasm interfaces.

Table 1. Tensions at *Oil-Protoplasm* and Related Interfaces

| Oil Phase | Aqueous Phase | Method | T_x in Dynes/cm | Reference |
|------------------------------------|---|-------------------------------|--|-------------------|
| Mackerel egg oil ¹ | Mackerel egg cytoplasm | Centrifuge-sessile drop | 0.1-2.6 | (8) |
| | Mackerel egg-extract ² | Du Nouy tensiometer | 0.8 | (5) |
| Daphnia egg oil ¹ | Daphnia egg cytoplasm | Centrifuge-sessile drop | 0.6-1.4 ³ | (7) |
| Olive oil ⁴ | Ameba cytoplasm | Centrifuge-sessile drop | 1.8-2.0 ³ | |
| Paraffin oil [oleic acid] | Valonia aplanospores | Oil-coalescency ⁵ | <2.5 | (11) |
| | Aging <i>Arbacia</i> eggs | | <3.0 | (2) |
| Liquid petrolatum | <i>Arbacia</i> egg cytoplasm | Flow-pressure | $<6 \times 10^0$ | (16) ⁶ |
| Oleic acid | | | $<5 \times 10^{-1}$ | (16) ⁶ |
| Oleum percomorphum | <i>Arbacia</i> egg-extract ⁷ | Drop-retraction ¹⁰ | 3.5-7.5 | (16) ⁶ |
| Oleic acid | | Flow-pressure | 0.5-1.2 | (15) |
| Cottonseed oil | | Flow-pressure | 5.7 | |
| Oleum percomorphum ⁴ | Asterias egg cytoplasm ⁹ | Devaux effect | 0 ⁸ | (12, 13, 14) |
| | Asterias egg-extract | Drop-retraction ¹⁰ | $n \times 10^{-11}$ $n \times 10^0$ ¹² | (16) ⁶ |

⁸ Zero interfacial tension occurs on cytolysis if oil is injected prior to cytolysis.

⁹ Cells cytolized by puncturing the germinal vesicle with a microneedle.

¹⁰ Calculated from $T_x = T_{\infty}(1 - \pi d_c^2/\pi d_e^2)$ but using $\pi d_c^2 = \pi d_e^2$. Accordingly, the calculated value for T_x is probably too high (cf. 17).

¹¹ Oil brought in contact with cytolytic residue, 1 minute after cytolysis.

¹² Oil brought in contact with cytolytic residue, 10 minutes after cytolysis.

Surface Activity of Intact Cytoplasm at Oil-water Interfaces

Harvey and his collaborators^{7, 8} devised methods for measuring oil-protoplasm interfacial tensions by applying the theory of the sessile drop to those oil drops normally present in cells or to those introduced into cells by microinjection. The imperceptible flattening which occurs by gravity is accentuated by applying known centrifugal accelerations with the centrifuge-microscope. The tensions at the surfaces of oil drops can be calculated from the degree of flattening at a given centrifugal field.

The micro-tensiometer, based on the flow-pressure through the orifice of a micro-pipette, was employed by Kopac.¹⁷ The micro-pipette which contains the oil is inserted into the cytoplasm of a cell with a micro-manipulator, so that contact between the oil and cytoplasm can be established. The micro-pipettes are calibrated by measuring the flow-pressures of the same oil with the pipette dipping in dilute buffer solutions. In the latter systems, tensions at the oil-buffer interfaces can be measured by classical methods. These data, together with those obtained by Harvey, *et al.*, are summarized in Table 1.

Oil-protoplasm interfacial tensions, when expressed in dynes/cm, are of a low order of magnitude. The tension-lowering activity of protoplasm and protoplasmic proteins can be demonstrated even more strikingly by recalculating the data given in Table 1. Oil-water interfacial tensions, except those of apolar oils, vary with the pH and salt content of the aqueous phase.³ The T_0 values which were used in recalculating the data are the tensions of the various oils in contact with an aqueous phase of about the same pH as that of cytoplasm, *i.e.*, pH = 6.8. In some cases, the T_0 -values were derived from other data.

The T_s values were taken from the same sources as those given in Table 1. The ratio, θ , which equals T_s/T_0 and varies inversely with surface activity, indicates the tension-lowering activity of the components in the aqueous phase. The interfacial tensions of the various oils used and their corresponding θ values are given in Table 2.

Protoplasm is capable of reducing the tension at most oil-water interfaces by very significant amounts, θ being generally less than 0.2. Protoplasmic derivatives show similar surface activities. Albumins are also surface-active but their activity at oil-water interfaces is not as pronounced as that of cellular extracts. Only when lecithin or similar substances have been added to the interface with albumin, is there a tension lowering of the same order as that found with protoplasm or protoplasmic proteins.

Surface Activity of the Residue from Rapidly Disintegrated Arbacia Egg Cytoplasm

By appropriate centrifugal fractionation, the residue from rapidly disintegrated Arbacia eggs (in 0.53M KCl) can be separated into the following fractions: (a) pigment vacuoles; (b) yolk granules; (c) mitochondrial granules; and (d) cytoplasmic matrix residue.^{9, 17}

The proteins of the cytoplasmic matrix as obtained by centrifugal fractionation are readily adsorbed at oil-water interfaces. These proteins, however, when in solution exist in the 3-dimensional or globular state. Some of the molecules which reach the interface undergo a 3 to a 2-dimensional shift. The unfolded, 2-dimensional protein molecule becomes insoluble in the aqueous phase and it does not become more soluble in the oil phase. Such molecules are therefore 'trapped' at the interface where they may be concentrated and packed by appropriate means. However, before such molecules can be packed, some of the molecules in the mixed population (3 and 2-dimensional configurations) will be forced out of the interface. Since the 3-dimensional protein molecules are water-soluble, they will be the ones

Table 2. Tension-Reducing Activity of Protoplasm, Cellular Extracts and Proteins

| Oil Phase | Aqueous Phase | T_0 | T_s | $\theta = \frac{T_s}{T_0}$ | Reference |
|---------------------------|------------------------|-------------------|------------------|----------------------------|-----------|
| Mackerel egg oil | Mackerel egg cytoplasm | 9 ¹ | 0.1 | 0.02 | (8) |
| | | | 0.6 ² | 0.07 | |
| | | | 1.8 ³ | 0.2 | |
| | Mackerel egg-extract | 7 ⁴ | 0.8 | 0.1 | (5) |
| Olive oil | Ameba cytoplasm | 10 ⁵ | 2.0 | 0.2 | (7) |
| Paraffin oil | Arbacia egg cytoplasm | 38 | 6 | 0.16 | (16) |
| Oleic acid | Arbacia egg cytoplasm | 7.5 ⁶ | 0.5 | 0.07 | (15) |
| | Arbacia egg-extract | 7.5 ⁶ | 0.6 | 0.07+ | |
| | | | 1.3 | 0.18 | |
| Cottonseed oil | Arbacia egg-extract | 12.0 ⁶ | 5.7 | 0.48 | (17) |

¹¹ Average at 1600-3200 \times gravity.

forced into the aqueous phase and only those molecules in the 2-dimensional state will remain. Accordingly, the saturation capacity of an oil-water interface depends on the extent to which the 3 to 2-dimensional shift is induced (see below).

Data on the ratio of expanded/compressed areas, K , of unfolded molecules were obtained at various surface pressures. The values for calculating K were derived from the simultaneous determination of tension-lowering as produced by a given number of protein molecules and the fraction of the oil-water interface which these molecules occupied.

The calculated K -values were then plotted against corresponding tension-lowering values. The value of K corresponding to an interfacial saturation of zero (extrapolation to zero surface pressure) was found to be 2.17. Where the interface is half-saturated, K equals 1.73; while at complete saturation K equals 1. Other values are: at 0.24 saturation, K equals 2.0; at 0.93 saturation, K equals 1.10.

The above K -values show that at oil-water interfaces under the experimental

conditions used there can be more than a 2-fold difference in area between expanded and compressed cytoplasmic protein molecules in the unfolded state. These are in agreement with data published by Neurath²⁰ for the areas of other expanded and compressed proteins (at water-air interfaces). Calculation of his data gives the following *K*-values: egg albumin, 1.69; serum albumin, 1.83; insulin, 2.14; and cytochrome-C, 2.21. Here the value of *K* is the ratio of expanded/compressed spreading areas at water-air interfaces of 1 mg of protein.

Protein Adsorption at Oil-Water Interfaces

The oils, tricaproin, *n*-butyl phthalate, or Squibb's Liquid Petrolatum have different adsorption curves, as might be expected from their obvious chemical dissimilarity. However, if to each of these oils is added enough oleic acid to make its concentration about 1 per cent, considerably higher amounts of proteins are adsorbed. Even more striking is the fact that one adsorption curve adequately accommodates the average determinations for each basic oil phase. The similar rates and amounts of adsorbed proteins show that these oils have acquired nearly identical surface-properties. The drop-retraction method was employed for these measurements.¹⁷

Pure oleic acid adsorbs cytoplasmic proteins rapidly and its interface becomes completely covered in less than 1 minute. The rate of protein adsorption on those oils to which oleic acid was added is probably influenced by the rate at which the less surface-active molecules in the oil become replaced at the interface by a monolayer (or more) of oleic acid. Oils which contain higher concentrations of oleic acid become completely coated with cytoplasmic proteins in less than 8 minutes. On the other hand, oils containing lower concentrations of oleic acid require considerably longer exposures to the proteins before their interfaces become entirely coated.

It is evident that the oil-water interface has a saturation capacity for cytoplasmic proteins and that this capacity depends on the oil phase and possibly on the proteins. For example, Liquid Petrolatum after being exposed to cytoplasmic proteins for 10 minutes is completely saturated when about 0.4 of its interfacial area has become covered by adsorbed molecules. However, Liquid Petrolatum + oleic acid (1 per cent), following a 10-minute exposure, becomes saturated with cytoplasmic proteins only when its entire interfacial area is covered. Other oils show either similar or different saturation capacities. Furthermore, their saturation capacities may be altered by adding a new component to the oil-phase, *e.g.*, the capacity of Liquid Petrolatum + lecithin (0.5 per cent) becomes 1.0 in less than 30 seconds (indicating complete coverage of the interfacial area).

These data¹⁷ show that oil-water interfaces will become completely coated with cytoplasmic protein molecules only under certain conditions. The oil must contain molecules which can form interfacial complexes with those protein molecules reaching the interfacial zone. For complete coverage of the interface, the complex must be stable enough to withstand the high surface pressures resulting from the adsorption of large numbers of surface-active molecules. In the case of oleic acid dissolved in oil, the interface becomes oil [oleic acid-protein] water (see stage E, Table 3), in which the oleic acid-protein complex has sufficient stability to endure surface pressures ranging from 12 to 15 dynes/cm.

Spontaneous Devaux Effect at Oil-Protooplasm Interfaces

Devaux was the first to describe that egg albumin forms insoluble monolayers at water-air interfaces, and later⁶ he reported on the adsorption of similar proteins at benzene-water interfaces. He observed that such interfaces in the presence of proteins might become folded or crinkled.* The amounts of protein required to produce this phenomenon were estimated to be just sufficient to form a monolayer

* See also "The Influence of Colloids on Crystalline Form & Cohesion," by W. M. Ord, London, 1879.

at the interface. This remarkable crinkling or folding at an oil-water interface by adsorbed proteins has been called the "Devaux crinkling effect" by Langmuir and Waugh.¹⁸ A similar crinkling which occurs on drops of certain oils when brought in contact with cytolyzing starfish eggs has also been called the Devaux effect.¹²

Similar phenomena were observed by F. M. Ascherson* over 100 years ago; his paper, presented to the Paris Academy of Sciences on Nov. 12th, 1838, was published in *Arch. f. Anat. Physiol.*, 1840, p. 44, and a translation forms the first paper in "The Foundations of Colloid Chemistry" edited for the Colloids Committee of the British Association by E. Hatschek (E. Benn, Ltd., London, 1925), under the title: "On the Physiological Utility of Fats and on a New Theory of Cell Formation Based on Their Co-operation and Supported by Several New Facts." Ascherson stated: "... coagulation in the form of a membrane occurs inevitably and instantaneously when albumin comes into contact with a liquid fat, and that consequently an oil drop cannot be surrounded even for a moment by an albuminous liquid without a vesicular membrane or a cell forming round it. For the sake of brevity I shall call the property of forming membranes by contact *Hymenogony*, and the membranes thus formed *Haptogen* membranes. . . . The formation of a few globules which do not become flattened again is perhaps the most delicate reagent for discovering in distilled water the slightest trace of an organic substance, and I must add that up to now I have not found any which passed this test completely." Ramsden studied the adsorption of albumin, which he found was thus denatured.^{21a}

Kopac reported^{10, 12, 14} that oil drops when injected into starfish eggs, under certain conditions, spontaneously increase their interfacial area by crinkling or folding. Experimentally introduced oil-drops (by microinjection) will not show the crinkling effect unless the cells are partially or completely cytolyzed. For example, every oil drop (*Oleum percomorphum*) when microinjected into *Asterias* oocytes produces the Devaux effect providing the cells are cytolyzed not more than 30 seconds later, the cytolysis being induced experimentally by puncturing the germinal vesicle with a micro-needle. The same reaction occurs on oil drops introduced within 15 seconds after cytolysis. Also 99 per cent of the oil drops microinjected into oocytes within 1 minute before cytolysis and 50 per cent, if introduced within 1 minute after cytolysis, give the Devaux effect.

The evidence, at present, suggests that the majority of proteins and protein complexes in protoplasm are bound together to form a protein-continuous phase so that they become essentially non-diffusible and hence relatively non-adsorbable. Such a conclusion follows from the fact that spontaneous Devaux effects are not obtained unless the cytoplasm is disintegrated (also discussed by Chambers¹). Following

* Ascherson also anticipated ultramicroscopic illumination, as the following quotation shows: "It can hardly be doubted that hymenogony acts under the influence of life just as it does in the chemist's test-tube. The irregular cells which I have found in ova, and the dull surface and slight irregularities which a practised eye fairly easily discovers on the globules in milk or yolk larger than $\frac{1}{80}$ mm, prove the existence of a haptogen membrane formed in the living animal. This skin appears to be the only cause of the spherical shape and of the isolation exhibited by drops of fat in plants and animals according to my observations; likewise in milk, where Raspail had already conjectured the existence of a membrane on the globules, and in artificial milk. I have shaken oil with distilled water and have found that all drops which can conform to hydrostatic laws assume a lenticular shape with thin, very transparent edges, while they preserve their spherical shape and black margins even in the largest volume of water, provided they have previously had an opportunity of coating themselves with a haptogen membrane by the aid of a little mucus or albumin. This very decided difference can be perceived most easily when a few drops of oil are shaken with water containing only a little albumin. It is then still possible to distinguish among the droplets, the diameter of which does not exceed $\frac{1}{700}$ mm, those surrounded by a membrane, which increase in number with the albumin content of the liquid, from those which have remained free. The latter are best seen by focusing the microscope exactly on the surface of the liquid and illuminating from the side." Zsigmondy first saw fine colloidal particles by similar illumination. ("Colloids and the Ultramicroscope," by R. Zsigmondy, Eng. trans. by J. Alexander, New York, 1909). EDITOR.

cytolysis, the protein-continuous phase is broken thereby releasing the protein molecules in a form which permits their adsorption on suitable oil-water interfaces. The Devaux effect can develop only if enough protein molecules accumulate and unfold to form at least one monolayer on the experimentally introduced oil-surface.^{10, 12, 14, 16, 18}

Protein phases bound together by experimental means also inhibit the development of the Devaux effect.¹⁶ Trichloroacetic or phosphotungstic acid produce a protein-continuous phase, albeit by precipitation, but under such conditions the components are obviously non-diffusible. No Devaux effects are produced after the introduction of either of these reagents into a cytolysing oocyte even though suitable oils were injected into the cell prior to cytolysis.

During the life of a cell, both proteins and protein complexes must at various times break away from the continuous phase and exist in solution in the aqueous phase. An equilibrium, in all probability, is maintained between the dissolved proteins and those anchored to the protein skeleton.²³ The concentration of such molecules in the aqueous phase is insufficient to produce spontaneous Devaux effects, however.

Danielli and Harvey⁵ conclude that the low values of oil-protoplasm interfacial tensions are due to the adsorption of a film of protein, probably a globulin, at the interface. It is important to recognize that non-protein substances frequently enhance the adsorption of proteins^{17, 22} and thereby yield low interfacial tension values. Danielli⁴ has shown that the addition of lecithin (in oleic acid) increased the surface activity at an oleic acid-water [albumin] interface. Lecithins and similar substances are present in living cells and derivatives of these substances also occur in the extracted cellular residues.

Evidence from studies of the Devaux effect indicates that the proteins of intact cytoplasm are not adsorbed in quantity by experimentally introduced oil surfaces. Such a situation would make the explanation of low tensions at oil-protoplasm interfaces rather difficult. One must therefore assume that these organized complexes which come in contact with the oil must have a high degree of intrinsic surface activity.

The above assumption is supported by the fact that tensions at oil-water [virus protein] interfaces are low,¹⁶ and it is also known that similar macromolecules (hemocyanins) do not spread at water-air interfaces unless dissociation into smaller units occurs.²¹

Our tentative interpretation is that the interface between oil and protoplasm is fundamentally an oil [PROTEIN-protein complex] water * system, instead of an oil-water [protein] system, especially in those instances where the oil is native to the cell (mackerel and *Daphnia* eggs). The tensions at either interface could be of the same order. The protein complex is defined here as the association of proteins with other large molecules (including proteins) by weak apolar, dipole-dipolar, ion-dipolar, or ionic bonds.

During the measurement of interfacial tensions by the flow-pressure method, it is possible that enough cytolysis is caused by the introduction of the experimental oil phase to release additional proteins and protein complexes from the protein-continuous phase. Here the interfacial system would be: oil-water [protein complex] in which the complexes may have the same status as other high molecular weight protein particles (mitochondria and viruses, for example).

General cytolysis, probably, involves not only a further breakdown of the protein-continuous phase, but also the dissociation of protein complexes out of which it is formed. If these complexes dissociate further, the interfacial conditions become similar to oil-water [protein + lecithin] systems in which the degree of tension lowering is a direct function of the oil phase, the nature of the proteins and of the

* The symbol, PROTEIN, represents the postulated protein-continuous phase of protoplasm.

complexes in association with proteins. Phospholipids of the lecithin type, because of their surface-active properties, are believed to be the most important of the complexes other than proteins to be released on cytolysis. In this review, lecithin generically represents all complex phospholipids which may be derived from protoplasm.

In summary, the change in protein organization on cytolysis in relation to surface activity at oil-water interfaces may be schematically represented as follows:

Table 3

NATIVE OIL-PROTOPLASM INTERFACES

A. oil [*PROTEIN*-protein complex] water

EXPERIMENTAL OIL-PROTOPLASM INTERFACES

Incipient cytolysis [Reversible]

B. oil-water [*PROTEIN* + protein complex]

General cytolysis [Irreversible]

Breakdown of protein-continuous phase and complex dissociation

C. oil-water [protein + lecithin]

Redistribution of lipid complex

D. [lecithin] oil-water [protein]

Interfacial complex formation

E. oil [lecithin-protein] water

It has been shown that various substances when introduced in the oil-phase may modify protein adsorption (p. 878), and lecithin is one of these substances. Thus at stage D, the oil phase becomes conditioned by the lecithin, which in turn promotes protein adsorption and thus increases the saturation capacity of that interface. The result is the production of interfacial complexes (stage E) in which the transfacial forces are of maximum magnitude. If these complexes completely cover the oil surface, the interfacial tension becomes zero (transfacial forces equal interfacial forces).

The ideal time for introducing the oil phase for spontaneous Devaux effects seems to be between stages B and C so that the proteins and protein complexes can be adsorbed just before their inevitable dissociation. Morphologically, such time corresponds to the first onset of cytolysis. At this time, protein complexes as well as lecithin and protein molecules are simultaneously within the field-force of the oil-water interface and, following interfacial dissociation, the solution of lecithin in the oil and adsorption of proteins can occur independently of diffusion rates. Introduction of oil surfaces at later stages is less effective because now both lecithin and proteins must diffuse toward the interface (in small aggregates or as molecules) before solution and adsorption of adequate amounts is possible. In these later stages, diffusion from the bulk phase to the interface becomes important.¹⁰

Cytolysis, which results in the breakdown of the protein-continuous phase, and then of the complexes, yields not only protein molecules of low molecular weight (one to several Svedberg units) but also minor complexes between these and lipophilic molecules. Most of the proteins and other protoplasmic components which have been studied *in vitro* are obtained in this condition. The study of 'native' cytoplasmic proteins *in situ* has only been broached.

Physical Changes of Muscle Related to Activity

OTTO MEYERHOF, M.D.

Research Professor of Biochemistry,
Department of Physiological Chemistry, School of Medicine,
University of Pennsylvania, Philadelphia, Pa.

Introduction

Investigators of the chemistry and physiology of muscle in the last two decades have been busy disentangling the chemical reactions concerned with the transfer of energy and with the time course and the implications of this energy transfer; but we should not overlook the fact that muscular contraction in itself is essentially a problem of colloid chemistry, or at least has many aspects of colloidal character. The contraction process can be traced to the change in shape and possibly hydration of protein particles, myosin micelles, in the anisotropic elements of the striated muscle fiber. A change in birefringence of these anisotropic discs coincides with the contraction and relaxation.

The recent work of Astbury^{1a} and others on x-ray patterns of myosin and muscle fibers (reviewed by the author in this volume) supplies us with a working hypothesis: the intramolecular changes in the chain-like myosin molecule, closely resembling the α - β transformation of keratin and the supercontraction of hair, are considered responsible for the contraction of muscle.

On the other hand, the study of the energy-yielding chemical reactions revealed some unexpected physical changes in muscle, which undoubtedly must also be explained by a change in the colloidal state of the protein, *e.g.*, the increase in transparency of the muscle during the splitting of phosphocreatine into creatine and phosphate. Moreover, other physicochemical changes, like change of pH, volume contraction, etc. can be only partially explained by the formation or decomposition of intermediary metabolic substances which consist of small "crystalloid" molecules. There always remains a superimposed effect, which has to be attributed to unknown changes in the contractile protein. Therefore, these studies add emphasis to the essential role which the protein plays in the shortening and development of tension during activity.

Of course, colloid chemistry has also some bearing upon the chemical mechanism of the intermediary reactions, insofar as the enzymes concerned are proteins, which in part possess a dissociable prosthetic group, called coenzyme. The relations between the colloid enzyme protein, the coenzyme and the substrate are of too general

a nature to be dealt with comprehensively in an essay on muscle chemistry. Nevertheless, recent findings indicate that some of these enzyme proteins may form a link between the metabolic reactions and the physical change in muscle, or that the contractile protein itself may function as an enzyme in the last step of the energy-yielding reactions.

The thermodynamics of contraction leads to the conclusion that physical changes of the contractile protein are related to great changes in energy. Besides the thermo-elastic heat exhibited by a resting muscle in stretching, the time analysis of the heat development of an active muscle reveals a fraction which is due to the dissipation of energy of "tension" during relaxation in isometric contraction.

Since several of these items have already been treated in other parts of this book, I do not propose to discuss them all in detail. I shall restrict myself to an outline of the connection between chemical and physical changes during muscle activity, stressing those phenomena which can be explained only partly by simultaneous chemical reactions.

Outline of the Chemical Reactions Related to Activity

The true mechanism of contraction is not known. The earlier theories of Helmholtz, Dubois-Reymond, Fick, Bernstein, von Fürth, etc. must all be discarded because they are either unfounded or based on misinterpreted experimental evidence. Various chemical reactions concerned with energy production for the mechanical work of muscle have been found since that period of classic physiology. Although these reactions are more or less indirectly connected with the contraction mechanism, knowledge of them is a necessary preliminary to the understanding of the transfer of energy and finally to all discussion regarding the possible mechanism of contraction. Only a brief review of these reactions will be given here. A more comprehensive report can be found in some recent reviews, *c.g.*, Meyerhof,^{2, 3, 4} Kalckar,⁵ and Lipmann.⁶ A fuller discussion was made in German in a review of 1937 by the writer,² and the physical aspects were discussed by von Muralto.⁸

The heat measurements of Hill (1913) and of Hartree and Hill (1921-1928) and the chemical investigations of the writer (1919-1923) established the fact that the fundamental process of activity is anaerobic, and that oxidation serves for recovery. This recovery involves the endothermic resynthesis of substances split during activity, whereby the energy for this involuntary synthesis is supplied by coupling with oxidation. This fundamental fact was recently doubted by Sacks.⁹ D. K. Hill¹⁰ in 1940 repeated and extended the experiments of his father, A. V. Hill, and showed again conclusively, that the oxidative heat is really the exact expression of the simultaneous oxidation coupled with resynthesis.

Three different anaerobic reactions were found to be related to activity and also to be linked to one another: (1) splitting of carbohydrate, preformed in the muscle as glycogen and hexose-6-monophosphate, into lactic acid via phosphorylated intermediaries and pyruvic acid; (2) splitting of phosphocreatine into creatine and phosphate; (3) splitting of adenosine triphosphate to adenylic acid + 2 phosphate via adenosine-diphosphate + 1 phosphate.

The coupling of these three reactions with one another and with oxidation is shown in the accompanying diagram, the arrows pointing to the direction in which the reactions proceed. The vertical connections between the arrows correspond to the coupling. The end products of the breakdown reactions are given on the right side of the diagram, together with figures showing the calories of total energy which can be derived from the splitting of the amounts of each primary product present in one gram of an isolated frog muscle under normal conditions. These figures are obtained by multiplying the amount present in unfatigued muscles by the heat of reaction. In this way, one can see that these potential reactions represent energy stores,

which become larger from top to bottom of the diagram, that is, the farther the reaction is away from the contraction mechanism.

The interrelationship of these reactions was first shown in studies on enzyme extracts of muscle, and was confirmed in the muscle *in vivo*. The lactic acid formation restores the phosphocreatine, broken down in the earlier stages of activity, while

the breakdown of phosphocreatine is able to restore the adenosine triphosphate, and the oxidation of carbohydrate can reverse every cleavage reaction of I, II and III. Although it is not completely proved that in muscle activity the partial breakdown of adenosine triphosphate precedes the splitting of phosphocreatine, this is probable for several reasons, and we take it provisionally for granted. While the dephosphorylation of adenosine triphosphate is the first known step in the chain of reactions related to activity, it does not preclude other unknown chemical reactions preceding this step, which in such a case would belong to the recovery instead of to the immediate working phase of muscle. However, the analysis of the physical changes makes it highly probable that this reaction occurs in a very early stage of contraction and development of tension. The lack of success in finding any other reaction preceding this step has induced some authors to connect it immediately with the contractile mechanism. This subject will be discussed further (p. 890).

Time Course of Heat Production and Thermoelastic Heat

Although I am not taking into consideration the electrical changes in the active muscle, which are the expression for the excitation process rather than for the contraction, something must be said regarding the development of heat, already discovered by Helmholtz, which may be taken as an indication of the energy production for the mechanical work. The well-known studies of Hill¹¹ and of Hartree and Hill¹² revealed the time course of this heat production and supplied in this way

the first tool for studying the coördination of the mechanical and chemical processes in active muscle. From the point of view of colloid chemistry, those phases of heat production have special interest in that the equivalent of heat is not a simultaneous chemical reaction, but a thermoelastic process. It is true that in anaerobic heat,

FIGURE 1. Analysis of the heat rate during tetanic contraction. Stimulus 0.2 sec 0° C. Continuous lines, heat; A, galvanometer record; B, curve of control heating. Dotted line, result of analysis in 0.1 sec. By interpolation the smooth continuous curve is obtained, showing heat outburst during tension development, small heat during maintenance of tension and large heat of relaxation. Broken line, isometric tension of muscle. (From Hartree.)

compared with oxidative heat, a fraction appears which has to be ascribed to a physicochemical change, namely, the neutralization heat of the protein "zwitterion" by the acids formed in severe fatigue. This reaction is not of a colloidal nature; it occurs also with amino acids and dipeptides. Moreover, the fraction of the anaerobic heat linked to this neutralization is much smaller than was formerly assumed.¹³ The muscle does not become acid in the earlier stages of anaerobic fatigue, and so long as no lactic acid is formed, the amount of heat to be attributed to a change in the ionization of protein is negligible.

The thermoelastic properties of the resting and active muscle are of much greater importance for an insight into the physical mechanism. In 1863 Heidenhain showed that a passively stretched muscle is warmed on stretching.¹⁴ This result, doubted for a long time, was fully confirmed by Hill and Hartree in 1920;¹⁵ they found that a resting muscle, passively stretched, behaves like rubber, in that it produces heat while being extended and cools when released. The total change is reversible except for loss of energy by viscosity. This corresponds thermodynamically to a negative coefficient of linear expansion. Woehlisch and Clamann,¹⁶ in a more detailed study, confirmed this phenomenon and measured a negative coefficient of linear expansion for small and medium elongations (up to 30 per cent from the resting length), but for stronger extensions they found the sign of the expansion coefficient reversed. It is not quite clear what role the connective tissue plays in this reverse of sign. In 1937 the problem was taken up again by Meyer and Picken,¹⁷ who investigated the effect of change of temperature on the elastic force exerted by a stretched, unstimulated muscle at constant length. A negative coefficient of linear expansion corresponds to a positive temperature coefficient of the elastic force.

Such a positive coefficient of force was found for moderate elongations and reversed its sign for larger ones, in agreement with Wöhlisch and Clamann. However, under a force of zero and practically resting length, the sign was also reversed—a fact not clearly shown in the results of other authors, but as Meyer and Picken point out, in complete agreement with the behavior of rubber. They consider the latent heat set free during stretching as a sort of heat of crystallization. The flexible primary-valence chain molecules become arranged in bundles by stretching and a lattice is formed, visible in x-ray diagrams of stretched muscle.

Possibly the expansion coefficient is also reversed during active contraction of muscle. Azuma¹⁸ found in 1924 in Hill's laboratory that during the onset of contraction the muscle is cooled by stretching and behaves, not like rubber, but like a normal solid body. It is questionable whether the system is in equilibrium and whether thermodynamic arguments are immediately applicable. But assuming that a new state of equilibrium is established by stimulation, one must conclude that the mobility of the links between neighboring chain molecules has disappeared, that the liquid bonds have become solid linkages, and that contraction is accompanied by a reversible coagulation.

Although the relation to the thermoelastic heat could not be definitely established, the phenomenon, called "relaxation heat" may be mentioned in this connection. Hartree and Hill discovered in 1921 that the initial heat which coincides with the contraction is given out in three distinct phases in the isometric contracting muscle: the first outburst takes place almost simultaneously with the tension development, and is proportional to it; a second, smaller amount is liberated during the maintenance of tension, and is proportional to the duration of the tetanic contraction and dependent upon temperature; a third part, amounting to 30 per cent of the whole, in tetani of 0.1-1.0 sec; coincides with relaxation. This relaxation heat corresponds to the dissipation of the elastic energy, when the tension disappears; it is, therefore, this part of the total heat which can appear as work instead of heat, if the muscle is allowed to shorten and to lift a load, instead of remaining fixed. An example taken from a publication of Hartree and Hill¹⁹ may illustrate this point:

| Duration of stimulus 0.4 sec. | | | | |
|-------------------------------|--------------------|-------------|--------------------|-----------|
| Form of Contraction | Total Initial Heat | Contraction | Heat of Relaxation | Work Done |
| Isometric | 96 | 61.5 | 34.5 | 0 |
| Work on ergometer | 95 | 89.5 | 5.5 | 26 |

The figures given here may illustrate still an other fact, discovered by Fenn in Hill's laboratory and called Fenn-effect:^{19a} the expenditure of energy is greater when the muscle is working by lifting a load than in isometric contraction, where it develops tension without shortening. As the example shows, the initial heat is in both cases 95 gcms. To this energy the work done on the ergometer has to be added: the working muscle develops an extra amount of energy just equal to the work done. The expenditure of energy in the active muscle is not fixed completely at the moment of the stimulus, but is regulated during the active contraction period according to the length and tension of the muscle fibers at every moment.

Time Course of Change of pH

The change of the pH of the muscle and also other physicochemical changes, to be discussed later, have this feature in common with the development of heat, that they reflect *in toto* the chemical changes brought about by activity. Even the time course corresponds roughly to these partly transitory (reversible), partly lasting effects. However, further change of H^+ concentration, due not only to the breakdown of metabolites but to the orientation of the contractile protein, becomes apparent by the use of methods possessing still less inertia and applicable to the muscle during onset, maintenance and disappearance of contraction.

It has long been known that the muscle becomes acid when greatly fatigued. This is due to lactic acid formation; but, contrary to former assumptions, this process has no immediate connection with contraction. In 1930 Einar Lundsgaard²⁰ discovered that a muscle, poisoned with iodoacetic acid, did anaerobic work without lactic acid

FIGURE 2. Change of pH of muscle during activity. Below, sum of tension development in kg per g muscle and 5 min, with 4 stimuli per min. Above, curve of change of CO_2 pressure. The downward slope of the curve means uptake of CO_2 and increasing alkalinity; upwards, increase in acidity. (From Meyerhof, Möhle, Schulz.)

formation ("alactacid contraction"), as the result of the breakdown of an energetically equivalent amount of phosphocreatine. After the phosphocreatine is completely split, the muscle goes into rigor, when the adenosine triphosphate is split also. In the normal muscle, under anaerobic conditions, part of the broken-down phosphocreatine is immediately resynthesized by coupling with lactic acid formation, as was shown by Meyerhof with Lohmann and Nachmansohn.^{21, 22} The change of pH, which normal and poisoned muscle undergo in these phases of anaerobic fatigue, was studied by Lipmann and Meyerhof²³ and with increased accuracy by Meyerhof, Möhle, and Schulz²⁴ using a manometric method, measuring at the same time the isometric tension developed in activity. The more acid the muscle was at the beginning (regulated by increasing the CO_2 content of the N_2 atmosphere) the more alkalinity was developed during the first 50-100 single contractions. While the poisoned muscle went into rigor after such an amount of activity, and the alkalinity remained unchanged, the normal muscle was able to do further work, the acidity developing at an increasing rate until complete fatigue. The alkalinity during the first part of anaerobic fatigue can be explained quantitatively by the splitting of phosphocreatine, because the second dissociation constant of the phosphoric acid group in this compound is much stronger than in the free phosphoric acid. The splitting of the phosphoric acid groups of adenosine di- and triphosphate, on the other hand, develops acid, because secondary phosphoric acid valencies are liberated; but this is veiled in the rigor of the poisoned muscle by simultaneous splitting of NH_3 from adenylic acid.

While these changes of reaction are of purely chemical origin, the studies of Margaria²⁵ and Dubuisson²⁶ in recent years have demonstrated a change of pH attributable to the physical state of the contractile protein and therefore of primary importance for the contraction mechanism. Margaria found that a frog muscle stained with a suitable indicator dye (brom-cresol purple or brom-thymol blue) showed a change in color during contraction equivalent to a shift of pH of about

FIGURE 3. Muscle chamber with glass electrode and amplifier set for measuring changes of pH of muscle during contraction and passive stretching. C_1 , glass electrode filled with $N/10HCl$ and closed on the lower end by a glass membrane; C_2 , indifferent electrode filled with Ringer solution and connected with a thread, F , lying on the muscle surface on the same place as the glass membrane, for avoiding disturbances by bio-electrical potentials (cf. the magnified drawing on the left.) The thread is fixed by a rubber cuff, (Gu) (m), muscle in isometric position. St , stimulating electrodes; CH , glass chamber with outlet E for filling with Ringer bicarbonate solution and gas mixtures. (From Dubuisson.⁶²)

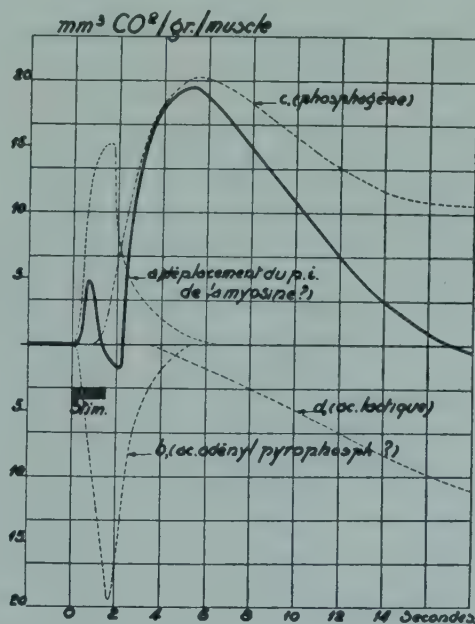

FIGURE 4. Record of galvanometer excursion in the apparatus of Figure 3, and analysis of the curve. Stim, stimulation, 1.5 sec. Continuous line, galvanometer reading. Alkalinization upwards; acidification downwards. The first peak on the alkaline side is probably due to the change of the isoelectric point of myosin during the onset of tension. See the broken line, giving the analysis of the galvanometer curve. The following peak on the acid side is to be attributed to the splitting of adenylypyrophosphate, the next big alkalinization to the splitting of phosphocreatine (= phosphagen), and the final downwards slope to lactic acid formation. (From Dubuisson.)

+0.5 to the alkaline side, and a similar, although less reproducible shift, if passively stretched during rest.

Finally Dubuissou measured with great accuracy the time course and the absolute amount of these changes of pH in different stages of activity, by the use of a glass electrode pressed on the surface of a frog muscle. While for longer time intervals a complete agreement is obtained with the manometric measurement, and while the chemical changes determined simultaneously explain quantitatively the resulting total shift of pH,²⁷ the measurement during the contraction itself reveals two more variations. In isotonic conditions the wave of alkalinity, attributed to the splitting of phosphocreatine, is preceded by a short deviation to the acid side, which coincides roughly with the duration of the contraction. But in isometric contraction of an unfatigued muscle this acidity change is preceded by a still sharper peak to the alkaline side, which has its maximum before the tension is fully developed. Now there are different reasons for assuming that the acidity wave, independent of tension, is the expression of the reversible breakdown of adenosine triphosphate, which is reversed by the breakdown of creatinephosphate; but the alkalinity peak during the development of tension is the same phenomenon as observed by Margaria. That this phenomenon does not originate in metabolism is evident from the experiments on stretching: if the muscle is completely unfatigued, passive stretching gives alkalinity changes amounting to a maximum of +0.2 pH (from pH 7.22 to 7.42). In this way the results of Margaria are at least qualitatively confirmed by an objective and accurate method. (The apparent shift of $\text{pH} = +0.5$, as given by Margaria, is probably too high.) It seems necessary to assume that the elongation of the protein chain, under stress, changes the isoelectric point. So far a similar phenomenon has not been observed on isolated myosin. Although the sign of the charge is opposite, an apparently related phenomenon has been recently reported in the stretching of nylon fibers.²⁸ Stretching shifts the isoelectric point approximately 1.2 pH to the acid side (from 3.9 to 2.7).

Volume Change During and after Contraction

The term "muscle contraction" refers to the diminution of length. Indeed, the question of whether the volume of a muscle changes at all during activity remained controversial during the whole period of "classical muscle physiology." As recently as 1925 the Hungarian physiologist Ernst²⁹ established without doubt a slight reversible diminution of volume during contraction. A more detailed study of this phenomenon in the Heidelberg Institute^{30, 31} showed that, in addition to the reversible change, there is a second important effect which continues beyond the contraction. The rather complicated curve of volume change can be explained, in large part, by the change of molecular volume of those substances which undergo transformation during activity. Such volume changes can be measured separately by allowing the same chemical reactions to go on in an enzymatic extract of muscle in suitable dilatometers. Roughly, the curve of volume change can be explained by the chemical reactions already discussed: splitting of phosphocreatine into phosphate and creatine is accompanied by volume constriction of 11.5 cc per mol, splitting of adenosine triphosphate into 1 mol adenylic acid and 2 phosphate with constriction of 20 cc per mol, desamination of adenylic acid to inosinic acid with 1 mol NH_3 formed with constriction of 21 cc, splitting of glycogen into lactic acid with volume dilatation of 24 cc per mol lactic acid. The summation of all these conflicting changes during a series of anaerobic contractions until complete fatigue gives a dilatation amounting to $15 \cdot 10^{-5}$ cc per gram of muscle. On the other hand, a muscle poisoned with iodoacetic acid shows only volume constriction, since lactic acid formation is absent, and the sum of the constrictions until onset of rigor amounts to $50 \cdot 10^{-5}$ per gram of muscle. But a volume change of only $30\text{--}40 \cdot 10^{-5}$ cc is calculated from the measured chemical reactions; the excess constriction, therefore, is to be attributed to a slow and

irreversible change of muscle protein. A similar result is found from a calculation of the effect in a normal muscle, since the sum of the chemical changes leads to a dilatation of $50 \cdot 10^{-5}$ cc per gram of muscle, while only $15\text{--}20 \cdot 10^{-5}$ mm are measured; therefore, in this case an unexplained constriction process of $30 \cdot 10^{-5}$ cc must be assumed independent of the changes of molecular volume of the metabolic substance.

The foregoing conclusion was also reached by measurements of the volume change in different forms of rigor and during permeation of an acid in absence of rigor. There always remains an additional constrictory effect, not accounted for by the simultaneous chemical reactions, *e.g.*, in the heat rigor only 40 per cent of the dilatation is found, as would follow from the lactic acid formed, corrected for the splitting of creatine phosphate. In the alactacid rigor of muscles poisoned with iodoacetic acid, approximately 180 per cent constriction of that calculated from breakdown of phosphocreatine and adenosine triphosphate is observed. Moreover, the permeation of valeric acid into a muscle is connected with a constriction of $20 \cdot 10^{-5}$ cc per gram of muscle without lactic acid formation or any change in the shape of the muscle.

These additional effects of constriction are always larger in muscles suspended in Ringer solution than in paraffin oil; probably they are due to shift of water. The uptake of water from outside is rendered impossible in paraffin oil; nevertheless, water can be exchanged between the fibers and the interfibrillar fluid, and between fibrils and sarcoplasm, and so on.

But for any theory of contraction, the transient volume changes which vanish with relaxation seem to be of much more importance. Ernst attributed these volume changes to electroconstriction of water caused by the liberation of K ions in the excitation process. But this is improbable. The volume change begins at the earliest 7σ after the stimulus, where the action current has already passed away. The volume constriction of the isotonically contracting muscle extends over the first half of the shortening time, whereas in isometric contraction the maximum of constriction coincides with the maximum of tension development. A second argument against the excitation theory of constriction lies in the great differences of volume change for the isotonic and isometric single contraction, while the stimulus is the same in both cases.

FIGURE 5. Muscle chamber for measuring volume changes during contraction. The muscle (gastrocnemius of frog) is mounted rigidly in the volume chamber (V). R, stimulating electrodes. A, electrodes for registering action currents. The muscle chamber is surrounded by a water jacket, W, maintaining constant temperature. The muscle chamber is filled with Ringer solution or paraffin oil, the capillary with hexane, and the meniscus of the hexane is photographed through a horizontally mounted microscope on a rotating photographion (kym) not shown in the figure. (From Meyerhof and Möhle.)

On the other hand, the reversible volume change is very probably linked to the fundamental physicochemical process, resulting in the tension development of the stimulated muscle. Ernst made the observation, confirmed and more closely investigated in Heidelberg, that for a smooth isotonic tetanus of 50 to 100 stimuli per sec. the corresponding curve of volume constriction is notched and exhibits as many notches as stimuli applied. Indeed, these notches correspond exactly to the summits of the constriction waves of single twitches, incompletely fused. The height of the reversible constriction in normal unfatigued muscles amounts to 10 times the constriction residue in single twitches; and the same is true for muscles poisoned with iodoacetic acid.

FIGURE 6. Curves of volume constriction of a muscle poisoned with iodoacetic acid during tetanic isometric contraction. For the experiments of this type, a larger volume vessel was used than that shown in Figure 5, and the tension developed by the contraction was recorded simultaneously by means of a torsion spring supplied with a mirror. Upper curve, I, II, III tension development during three 2-sec tetani. Lower curve, volume constriction. Diminution of volume is drawn upwards. Scale refers to the actual change of volume measured. Note: steep change during onset of tension, continuously increasing constriction during maintenance of tension, small decrease during relaxation and a high remainder of constriction which is cumulative. (From Meyerhof and Hartmann.)

The volume change in the gastrocnemius muscle of the frog is not influenced by the initial tension nor by passive extension of the muscle during contraction. But for muscles with parallel fibers it was reported by E. Fischer³² that with high initial tension the sign of the volume change was reversed, and a transient volume increase occurred. If this result is confirmed, it would stress the argument that so far as the reversible part of the volume change is concerned, physical factors are involved. These factors may consist of a shift of water between the contractile micelles and the surrounding fluid, and the like.

Changes of Transparency

It has been known for a long time that some smooth muscles become opaque or less transparent during contraction. That transparency to light changes during activity in the striated muscle was first observed by von Muralt and von Baeyer in the Heidelberg Institute.³³ The effects which outlast the contraction, can be attributed to the two main processes known to occur, *i.e.*, to splitting of phosphocreatine

which causes the transparency to increase, and to lactic acid formation which causes it to decrease. The latter effect is an indirect one and happens only when the muscle is immersed in Ringer solution. It is caused by the uptake of water. Immersed in a gas or in paraffin oil, the muscle does not become less transparent by forming lactic acid. But the increase in transparency, due to splitting of phosphocreatine, is independent of the surrounding medium and can, therefore, be studied most accurately in a muscle suspended in either nitrogen or oxygen. In both cases curves are obtained which give the clearest and truest picture of the simultaneous turnover of phosphocreatine. The reason why this metabolism results in a change of scattering of light is not known, but the effect has something to do with the colloidal state of protein in the muscle.

A change of transparency can be brought about both by change in scattering and by change in absorption of light. This subject was thoroughly investigated by Buchthal and Knappeis³⁴ using single muscle fibers. By the use of a very ingenious method—putting the muscle fiber into a ball-photometer (“Kugelphotometer of Ulbricht”), whereby the sum of light scattered in all directions is measured—they can distinguish between increase in scattering and true absorption, and can apply this procedure also to a fiber during contraction.

The light transparency decreases during isometric contractions. This is mainly due to increased scattering, but also partly to increased absorption. About 2 to 5 per cent of the extinguished light of the primary beam is absorbed in accordance with the Lambert-Beer law. Besides the absorption increase during contraction there is a small summing up of absorption after a series of contractions, amounting

FIGURE 7. Record of volume change on a photographion, rotating with high speed. Volume chamber of Figure 5. Constriction downwards. Isotonic contraction of muscle. B, tetanic stimulation with 50 stimuli per sec; C, with 100 stimuli per sec. Notice the notches corresponding to the number of stimuli. Below, recording of time in 1/10 sec. (From Meyerhof and Möhle.)

to 0.8 per cent of the total absorption. It is not possible to give an unambiguous explanation of these effects, except that elements having the magnitude of wave lengths of visible light change their optical properties, while the length of the fiber remains unchanged. This can be made more precise by recording the diffraction spectra of single muscle fibers and the whole muscle. The cross-striated fiber gives a grating constant of 2.10μ in agreement with the height of the single compartments of 2.18μ . From the form of the spectral lines of this diffraction grating during rest, contraction, and extension of the muscle, it appears that the light becomes more scattered in the direction of longer angles during contraction, as well as during extension, which seems to show that in both cases the micellar elongated elements of the resting fiber become more oriented in parallel.

Change of Double Refraction

As is well known, voluntary muscle is striated because the muscle fibers, or their constituents the fibrils, are built up of discs with alternating optical properties, one layer (the so-called I-layer) being nearly isotropic, but according to W. T. Schmidt³⁵ actually possessing a weak double refraction; the other layer (so-called A-layer, formerly named Q-) possessing a high degree of birefringence. After this fact had been established by Brücke (1858), von Ebner showed (1882) that this birefringence was reversibly decreased during isotonic contraction—the so-called negative variation of double refraction. Later work proved conclusively that only the anisotropic discs are actively contractile, the I-layers following passively or being stretched in isometric contraction.

The theory which applies to this birefringence was developed by Wiener in 1909. He proved by mathematical deduction that besides a crystalline double refraction, which is shown by a condensed homogeneous substance on account of its atomic structure, another kind of double refraction must exist for a mixed body where elongated micelles or rodlets, small by comparison with the wave-length of visible light, are in regular order imbedded in a second medium of a different refractive index. Under such conditions "form birefringence" results, even when the material

FIGURE 8. Record of change of double refraction of a frog sartorius during isometric contraction. The upper thin curve is the tension curve of the muscle notched by a tuning fork of 250 vibrations per sec for recording time. The upwards displacement of the Fizeau-Foucault fringes to shorter wave lengths corresponds to a diminution of birefringence. Note the two humps during increase and decrease of tension. Vertical line R, stimulus. (From von Muralt.)

of the rodlets and that of the surrounding medium are both singly refractive in themselves. In order to find out the amount of double refraction of form besides a possible amount of crystalline double refraction, it is necessary to substitute for the natural surrounding medium other liquids with different refractive indices. Starting with liquids of high refractive index and descending to lower indices, the total double refraction ought to decrease in the same sense until a minimum value is obtained, from which point on, with liquids of still lower values for the refractive index, the double refraction rises again. The change of birefringence from the start to the minimum corresponds to the form double refraction, while the remaining birefringence at the minimum is crystalline double refraction.

This method was applied to muscle by Schmidt in Giessen³⁵ and still more thoroughly by Weber and Noll.^{36, 36a} It was found that the greater part of the birefringence was due to the micellar structure and only about $\frac{1}{3}$ was crystalline. Weber showed that the same was true for threads of undenatured myosin, the contractile protein of the muscle.³⁸ Some years before, in 1930, Muralt and Edsall³⁷ had shown that solutions of undenatured myosin exhibited birefringence of flow

and abnormal viscosity, indicating that the solution consists of elongated particles of sub-microscopic dimensions, and they thought it probable that these particles were identical with the micelles of the doubly refractive discs. This was confirmed by the investigations of Weber,³⁸ who devised a highly valuable scheme for making undenatured myosin threads by squirting the Edsall-Muralt sol through a fine hole into water. These threads are extensible and elastic, and exhibit typical heat rigor by warming to 40° C. They show a birefringence which, in the extended threads, corresponds exactly to that in the anisotropic elements of living muscle, which take up 40 per cent of the volume of the fiber. Accordingly, the birefringence of the extended threads is 2.5 times the overall birefringence of the fiber. The results of these measurements in connection with x-ray and ultracentrifuge studies permit calculation of the dimensions of the micellar pattern in the birefringent discs. According to Weber, we must assume, per square millimeter cross section of muscle, about 15 billion rodlets, each composed of 15 to 20 myosin molecules in a more or less parallel bundle. These fill 70 per cent of the micelles, while the remaining 30 per cent is water, in which the protein molecules are swollen and can shift. The length of the rodlets, identical with the length of the "backbone" of the protein molecules, is about 500 Å, the width 50 Å, while the distance between neighboring micelles is less than 70 Å. The medium in which the micelles are suspended is a salt solution; a thread of myosin, swelling in a solution of myogen, does not take up any of the myogen, while it takes up sugar, because the distance between neighboring rodlets in the birefringent discs, as in the myosin threads, does not allow entrance of foreign protein.

As F. O. Schmitt³⁹ has pointed out, the rodlets are most probably interconnected by anastomosing chains. Moreover, water plays an important role in maintaining the specific structure, and may, in itself, be responsible for the long spacing equatorial diffractions in x-ray diagrams of fresh muscle. If this is true, the micelles might be considerably thicker than the 50 Å mentioned above.

In 1932, von Muralt in the Heidelberg Institute was the first to measure and to register the change of birefringence during contraction. He photographed on a highly sensitive film the Fizeau-Foucault fringes which appear by prismatic dispersion of polarized light after its passage through a birefringent medium. When the birefringence changes, then the black fringes which result from interference move to other wave-lengths. In isometric contraction when, by special arrangements, all movement of the muscle was carefully avoided, a diminution of about 30 per cent was obtained. The curve of change showed two spikes, one during onset of tension and one during relaxation, while during the interval of maintained tension a saddle was formed. Muralt interprets this curve, which is analogous to the curve of isometric heat obtained by Hartree and Hill¹² as due to the occurrence of two distinct processes which affect the molecular pattern of the micelles, one during rising and one during falling tension.

Recently several investigators have measured change in birefringence of striated and smooth muscle, using more simple and less exact methods than von Muralt. They either used the Babinet compensator mounted on a microscope, or a wedge of mica for obtaining interference fringes, which move with change of double refraction. Bozler and Cottrell⁴¹ confirm the drop of 30 per cent in birefringence in an isometric twitch of a frog sartorius, though only with small initial tensions, and not with zero tension nor with high tension. They attribute it to the shortening of the A-bands and extension of the I-bands in the striated fibrils. However, this shortening in the length would be accompanied by an increase in thickness; therefore, pure geometrical reasons would not lead to a change and we would have to assume the same factor effective here as in isotonic contraction. Buchthal and Knappeis,⁴² using single fibers, also find a decrease of birefringence in isometric contraction, and a slowly developing diminution during fatigue, which they attribute to lactic

acid formation and which is absent in muscles poisoned with iodoacetic acid. On the other hand, Fischer⁴³ and Bozler and Cottrell⁴¹ found that the double refraction of smooth muscle, which concerns the muscle fibers *in toto* instead of the discs in the striated muscle, increases by extending the muscle proportionately to the length, but does not change, in general, with tension. The increase with length can be interpreted as due to an improved orientation of the chain molecules by stretching.

It may be mentioned in this connection that the increase in "impedance," the electrical resistance to alternating current, which was observed during contraction by Bozler (1935)⁴⁴ and Dubuisson (1937),⁴⁵ may have a theoretical relation to the changes in birefringence. The curves of the changes in impedance, recorded by these authors during isometric tetanic contractions of striated muscle, are very much like those of volume change and are obviously composed of two different processes, one quick and synchronous with the change of tension, the other slow and outlasting the mechanical response. While the latter part probably depends upon the permeability of the cell membranes, altered by the influence of metabolites—splitting of phosphocreatine (cf. Dubuisson)⁵⁵—the quick reversible increase in impedance may be due to a change of dielectric constants. As Fischer³² has pointed out, Wiener's formula determining the form birefringence of a mixed body has been derived from Maxwell's equations, and is based on the fact that the dielectric constants in the direction of the long axis of the rodlets are different from the constants in the direction perpendicular to the long axis. In consequence, any change of form birefringence of the mixed body must be accompanied by a change in impedance.

Colloidal Behavior of Muscular Tissue and of Isolated Myosin

While the actual change of the colloidal properties of muscle protein during the state of contraction can be detected only by indirect methods, the permanent change in greater degrees of fatigue can be observed by simpler means. It was reported by Saxl⁴⁶ in 1906, from Fürth's laboratory, that in the rigor of death, the solubility of muscle protein was diminished when measured by extraction of the muscle tissue with 10 per cent ammonium chloride solution. Decrease of the power to bind water, with increase of fatigue, was observed by Meyerhof and Lohmann (1924),⁴⁷ since the volume of the same amount of muscle tissue extracted with 10 per cent NaCl solution on a Buchner funnel becomes smaller with progress of fatigue and "the sheer aspect of the more or less swollen tissue enables us to state how far the muscle was previously fatigued."

A quantitative study of the solubility of muscle protein after onset of rigor and after prolonged stimulation was made by Deuticke (1930).⁴⁸ He found that the solubility of protein extracted by 0.11 mol phosphate solution of pH 7.5 decreased gradually with the time of anaerobic fatigue. The protein content of such extracts, always made in the same way, diminished after stimulation of the muscle; 3.3 per cent after ½ hour, 8.8 per cent after 1 hour, 13-17 per cent after 2½ hours of stimulation.

As Weber³⁸ reported in a preliminary note, this change of solubility concerns the myosin exclusively. Moreover, even slight degrees of fatigue bring about some loss of solubility, as may be seen from the accompanying chart drawn after Weber, and this change in solubility is completely reversible with recovery (cf. also Kamp^{38a}). In the comprehensive studies of Weber the fact was definitely established that myosin is the contractile protein, and that it is exclusively located in the doubly refractive elements of the muscle. Myosin has the properties of a high-molecular globulin. It is insoluble in water and in dilute salt solutions, soluble in KCl solutions over 0.04*N*, but also in this case it can be dissolved up to 2 per cent only on account of its high viscosity. With higher concentrations gels are formed.

The accompanying table shows the distribution and physicochemical properties of the different proteins in muscle.

Proteins of Rabbit Muscle, According to Weber³⁸

| | In % of Muscle-Protein White Muscle | Red Muscle | Isoelectric Point | η | Molecular Weight |
|------------|--|------------|----------------------|--------|------------------|
| Myogen | 22 | 17 | 6.3 | 1.04 | 81,000 |
| Globulin X | 22 | 17 | 5.1 | 1.14 | 140,000-180,000 |
| Myosin | 39 | 39 | 5.4 | 10.0 | $\sim 10^6$ |
| Stroma | 17 | 27 | | | |

Myogen, a protein of albumin nature, is located in the sarcoplasm, globulin X presumably in the isotropic discs. The content of 39 per cent of myosin corresponds exactly to the volume of 40 per cent, taken up by the anisotropic discs.

The molecular pattern of myosin was investigated by Boehm and Weber,⁴⁹ Meyer and Picken¹⁷ and recently with much improved technique by Astbury.¹ Since the

FIGURE 9. Change of solubility of muscle protein during anaerobic fatigue of the muscle. R, resting muscles. A, working muscles. Left, strong fatigue; right, slight fatigue. White area, dissolved myosin; shaded area, myogen and globulin X; dark-shaded area, residual nitrogen. Note that only myosin changes its solubility during fatigue. Scale: soluble N divided by total N. (From Weber.)

latter author has described his results in this volume, I may refer to his paper. According to him, myosin exists like keratin in the three forms, so-called α and β and supercontracted. The contraction of muscle is caused, according to Astbury, by a folding of the backbone of the myosin molecule, consisting of polypeptide linkages. Such "supercontraction" could be produced artificially in sheets of myosin, and while the α -form shows a diminution in length of 50 per cent compared with the stretched β -form, supercontraction further diminishes the length of the α -chain by 25 per cent, so that the final contracted length would be 38 per cent of that of the most extended length.

In the opinion of the writer, these quantitative relations appear as a weak point of an otherwise very attractive hypothesis. The birefringent discs can contract, as may be seen from histological photographs, to at least a quarter, that is by 75 per cent of the normal resting length, while starting with the stretched state of 200 per cent elongation of the relaxed muscle, the contraction in length, compensated for by an increase in thickness, would be to an eighth part. Some authors have reported still greater contractions. According to Studnitz,⁵⁰ muscle fibers of *Astacus* shorten to 30 per cent of their resting length; the actively contracting anisotropic discs, forming about 50 per cent of the fiber, therefore would shorten to 15 per cent of the resting length. Engelmann⁵¹ in an earlier publication observed in striated muscles

of insects contractions of the anisotropic elements to 5 per cent of their initial length! It seems therefore necessary to assume either a much more complicated folding of the long-chain molecules than in supercontracted hair or, besides folding, a gliding of the chains and a redistribution of water, as was assumed by the "classical" school of physiologists.

The stability of myosin sols is strongly influenced by ions. Curiously, K salts are the best suited for keeping myosin in a stable solution in distinction to Na, NH_4 , or Li, as was observed by Greenstein and Edsall.⁵² L. J. Mullins⁵³ in Fenn's laboratory discovered recently that myosin combines much easier with K ion than with Na ion. As is well known, the interior of the muscle fiber contains exclusively K, while Na is located in the surrounding interfibrous space. This fact may be explained tentatively by the preferential affinity of myosin to K. This K ion would maintain the myosin in a state of solvation in the micelles of the anisotropic elements.

Hypotheses Connecting the Phosphorylating Mechanism with Contraction of Myosin

It was tempting to the biochemists to test whether the first known chemical process to occur after stimulation,* the partial dephosphorylation of adenylypyrophosphate (= adenosinetriphosphate) would have an influence on the physical state of myosin. Some investigations of recent years seem to show that this is possibly the case.

In 1939 Engelhardt and Ljubimova⁵⁴ found that the enzyme adenylypyrophosphatase, by which the labile phosphate groups are split off, is contained in the myosin fraction of muscle protein. Because of this, the authors themselves and several others were inspired to look for a physical change in myosin in the presence of adenylypyrophosphate. In January, 1941⁵⁵ the Russian authors reported that myosin threads made according to Weber and attached to a sensitive torsion balance show a reversible increase in extensibility, which can be measured on the balance, when they are immersed in a solution of 0.0025 mol adenylypyrophosphate. This extensibility is dependent upon the native state of the myosin and is destroyed under the same conditions under which the enzymatic activity of myosin toward adenylypyrophosphate is destroyed.

Independently of this research, Needham, *et al.*⁵⁶ measured the double refraction of flow of myosin sols of Edsall-Muralt and the influence of different substances thereon. Adenylypyrophosphate diminishes this double refraction in very low concentration, *e.g.*, 0.004 mol, while other salts have a similar effect in a hundred times higher concentration. The effect of adenylypyrophosphate is reversible, and the return of the initial flow-birefringence is exactly proportional to the dephosphorylation of the adenylypyrophosphate caused by the enzymatic activity of myosin. Moreover, adenylypyrophosphate protects the myosin sol against the formation of an irreversible gel by other salts, allowing the sol to return to its original value of birefringence.

In recent publications from the same laboratory these findings were extended. D. M. Needham⁵⁷ and K. Bailey⁵⁸ were unable to separate by any means the enzymatic activity from myosin in its native state. The activity decreases in exact proportion to the denaturation of the myosin sol. Pure myosin causes only the first labile phosphate group to be split up, that is, the reaction: adenosine triphosphate \rightarrow adenosine diphosphate; the dephosphorylation of adenosinediphosphate to adenylic acid is caused by a second enzyme. The authors assume therefore that the enzymatic activity is directly bound to the native myosin.

In their latest publication of July, 1942, J. Needham *et al.*⁵⁹ report quantitative

* I am not discussing here the excitatory process. This process may be connected with the release of acetylcholine from the nerve end-plates; but how this release starts the excitatory wave, which propagates over the muscle is not known. Only this propagation induces the fundamental process of contraction itself.

results: "When a myosin sol is treated with adenylypyrophosphate at concentrations as low as 0.004 *M*, the flow birefringence is reduced by some 40-60 per cent, the anomaly is unaffected, and the relative viscosity is reduced by some 20 per cent. The subsequent return of both to their original values, which may take from a quarter of an hour to several hours, is accompanied by the splitting off of inorganic phosphate from the adenylypyrophosphate." This is repeatable on the same sample of myosin by new additions of adenylypyrophosphate. The effect is strongly specific, and is not given by adenosinediphosphate or any other phosphorylated compound.

Kalckar,⁶⁰ in a theoretical argumentation which preceded these experiments, discussed the possibility that myosin may take up phosphate from adenylypyrophosphate in the contracted state and would relax when its phosphate is transferred to other phosphate acceptors like hexosemonophosphate. In this way the energy of the dephosphorylation of adenylypyrophosphate would be transferred to the contractile mechanism. Indeed, all considerations of the mechanism of contraction should visualize the thermodynamic aspects of this question. As was found by the thermochemical measurements of Meyerhof and Lohmann,⁶¹ the "energy-rich phosphate bonds" of the adenylic system have accumulated the whole energy (heat and free energy) of the anaerobic breakdown of carbohydrate (24,000 gcal per mol adenylypyrophosphate or per mol lactic acid). The dephosphorylation of the adenylypyrophosphoric acid must transfer this energy to the working system, either directly or indirectly.

The experimental stage of this problem has only just started and it seems premature to draw definite conclusions regarding this mechanism from the above quoted experiments of Engelhardt and Needham. Important progress will probably be achieved in this field in the near future.

The Capillary Circulation

EUGENE M. LANDIS

Professor of Internal Medicine, University of Virginia, Charlottesville, Virginia

The capillary network very appropriately has been called "the workshop of the body." With the heart as pump, the arteries, arterioles, venules, and veins serve as the conducting tubes which transport blood to and from this workshop. The reactions of the larger portions of the circulatory system were known in detail long before the capillaries were studied intensively. Yet, it is only in the capillary network that the circulating blood comes into intimate contact with the tissues. Through the walls of the blood capillaries must pass the water, dissolved salts, oxygen and nutrient substances required by tissue function. Water, carbon dioxide, and other products which arise from tissue activity can be carried away by the circulating blood only after they have passed by diffusion or absorption through these same walls. The brief review* which follows is concerned chiefly with the properties of the capillary network and some of the major forces which control the movement of water, dissolved substances and gases through the walls of the capillaries either from the blood to the tissue spaces, or from the tissue spaces to the circulating blood.

General Considerations

The blood capillaries differ widely in diameter, length and the nature of their connections with the smallest arterioles and venules. Blood pressure and rate of flow vary not only in adjacent capillaries but also in the same capillary from moment to moment. Hence, while the single capillary is the true unit of interchange between blood and tissue, it must be emphasized that these units are by no means identical, and that any "average" figures must take into account the wide range of normal variation. With this reservation, an average mammalian capillary can be said to be approximately 0.25 to 0.75 millimeter long and 2 to 15 microns in diameter, depending upon its state of contraction. The wall of the capillary is composed of thin, plate-like endothelial cells placed edge to edge to produce an uninterrupted

* In the interest of brevity the references given are limited to a few monographs or comprehensive reviews in which extensive bibliographies can be found.

membrane about one micron in thickness, except for the localized bulge containing the nucleus of each endothelial cell. The apposed edges of the endothelial cells are bridged, or made tight, by an intercellular substance or cement concerning which little is known except that, although usually impervious, it will under certain conditions permit particulate matter or even leucocytes to pass through. These bodies apparently pass between the endothelial elements; the openings in the intercellular substance which permit their passage; they then close again tightly without disturbing the movement of fluid to any great extent. In some diseases, however, this intercellular substance seems deficient, and minute or even larger hemorrhages can occur. It should be noted that deficiencies in this intercellular substance are not necessarily associated with abnormalities in the function of the remainder of the capillary wall.

The endothelial cells, on the other hand, normally permit water and small molecules to pass easily, but prevent molecules of colloidal dimensions from passing in either direction. When these endothelial cells are injured their permeability increases to such an extent that molecules of colloidal size, *e.g.* proteins, can pass easily, but particulate bodies such as India ink or erythrocytes are still retained as long as the membrane is not physically torn or ruptured. Therefore, even in the capillary unit itself the functions and properties of the intercellular substance differ from those of the endothelial membrane proper. It is the endothelium which is predominantly concerned with interchange between the circulating blood and the tissues.

For many years the capillary network was regarded merely as a system of thin-walled vessels whose function it was to conduct blood between the tissue cells in whatever quantity the arterioles might supply. According to this concept, flow through the capillaries was entirely dependent upon the constriction or dilatation of the arteries and arterioles. The extensive studies of Krogh,³ and Lewis⁵ have summarized an impressive mass of evidence, showing that the capillaries are independently contractile, and that they are capable of responding individually in a delicate manner to the circulatory needs of the immediately adjacent tissues.

Krogh's original observations led him to believe that the endothelium was inert and that the contraction of the capillary was produced by certain Rouget or adventitial cells, scattered along the capillary wall. Recent evidence indicates that, in certain animals at least, the endothelium is also capable of contraction. For the present discussion the exact location of this contractile power is a matter of academic interest. The important fact is that, while arterioles control blood flow to a considerable extent, the capillaries are also able to respond separately and individually to localized tissue needs.

Capillaries dilate in response to local heat, accumulation of carbon dioxide or acid metabolites, local injury, drugs such as histamine, and nervous impulses induced by the axone reflex, or by stimulation of the vasodilator fibers of the sympathetic nervous system. They constrict in response to local cold (except excessive cold which produces injury and thereby dilatation), very slightly alkaline solutions, vasoconstrictor impulses from the sympathetic nervous system, hormones such as epinephrine or pituitrin, and absence of carbon dioxide or acid metabolites.

Thus the diameter of the capillaries is determined by interaction between (a) composition of the tissue fluid surrounding the individual capillaries, (b) composition of the blood flowing through the capillaries, (c) nervous stimuli, and (d) certain naturally occurring hormones. Even with this delicately and locally adjustable system, the blood stream, which serves as a transporting medium, is still separated from the tissues it supplies by a single layer of endothelial cells forming the walls of the capillary vessels. Obviously the interchange of substances between blood and the fluid bathing the tissues must depend fundamentally upon the properties of this membrane and the forces acting upon the fluid within and without the membrane.

Factors involved in fluid movement

(a) **General nature of the capillary endothelium.** While the cross-sectional area of a single capillary is extremely small, the collective cross-sectional area of all the capillaries in the body is roughly one thousand times greater than that of the aorta. Blood moves through the aorta at an average speed of 0.5 meter per second, but the greater cross-sectional area of the capillary network slows the average movement of capillary blood to 0.5 mm per second. In individual capillaries, however, flow is extremely variable, ranging from 0 to 3 mm per second, depending upon constriction or dilatation of the capillary and of its supplying arteriole.

It follows that the area of capillary wall available for fluid interchange is relatively enormous. Krogh³ estimated that if a man's muscles weigh 50 kg and his capillaries number 2,000 per sq mm, their total surface would be 6,300 sq meters. In the horse, dog and frog, 1 cc of blood is exposed in the capillary network to a filtering surface of 7,300, 5,600 and 2,700 sq cm respectively. Krogh estimated also that the total surface of capillary wall in the body of an average-sized man must exceed 6,300 sq meters, or 68,000 sq ft. In other words, the collective area of vascular endothelium in the adult human body can be visualized as a microscopically thin membrane three feet wide and over four miles long. Obviously, very rapid interchanges are favored by areas of this magnitude.

The capillary wall is also highly permeable, since it permits fluid to pass much more easily than do other cellular membranes so far studied quantitatively. Strictly speaking, the permeability of a membrane should be defined in terms of units of volume or mass passing through unit area and thickness of membrane in unit time under the influence of unit hydrostatic or unit osmotic pressure. Using the term "permeability" in this limited sense, the capillary endothelium in the mesenteric vessels of the frog can be compared roughly with certain other cellular membranes.

It has been shown that, under an osmotic pressure of one atmosphere, water passes through the membrane of the sea-urchin egg cell at the rate of 0.1 cubic micron per square micron of surface per minute. The membrane of the human erythrocyte is more permeable; under this same pressure water passes at the rate of 3.0 cubic microns per square micron of surface per minute. According to micro-injection experiments carried out on single capillaries of the frog's mesentery, a change in hydrostatic pressure of 5 cm of water modifies the filtration rate by 0.03 cubic micron per square micron of surface per second, which corresponds to a filtration rate of 370 cubic microns per square micron of surface per minute under a pressure of one atmosphere. These calculations indicate that fluid filters through the frog's capillary wall over 100 times as easily as through the membrane of the human erythrocyte, and over 3,000 times as easily as through the membrane of the sea-urchin egg cell. This high grade of permeability enters into any consideration of the physiology of the capillary network, one function of which is to distribute water and dissolved substances throughout the body efficiently and rapidly.

The significance of an extensive filtering area combined with great permeability can be illustrated by a calculation which, on account of the assumption made, is admittedly more interesting than important. Assuming that the human capillary wall in general possesses a permeability to fluid similar to that of the frog's mesenteric capillaries, the total plasma volume of a man would be filtered through his calculated 6,300 sq meters of capillary surface within ten seconds at a capillary blood pressure of 10 mm Hg if there were no force retaining fluid within the blood capillaries. Actually, the vasomotor system normally prevents the entire peripheral vascular bed from opening simultaneously and, in addition, the colloidal constituents of blood plasma, by developing a colloidal osmotic pressure, limit the loss of fluid from the blood stream. Only in widespread injury of the vascular endothelium would it be possible for fluid to leave the vascular system at such a rapid rate.

The movement of fluid between blood and tissue spaces varies in both rate and

direction. Hydration, dehydration, change in posture and exercise affect the total volume and the water content of the blood, but the variations are kept within safe physiological limits except under the most drastic conditions. Blood volume responds quickly to physiological needs and under pathological conditions shows great alterations, but the healthy organism strives to keep the general level constant. When water is taken by mouth, its absorption from the gastro-intestinal tract rapidly produces dilution of the blood during the period when the extra fluid is being transported throughout the body. Before the excretion of excess water by the kidneys begins, some of the excess fluid passes into the tissues. If the excretion of water by the kidneys is delayed for any reason, both hydremia and temporary storage in the tissues are accentuated. Limitation of water intake is accompanied, on the contrary, by concentration of the blood, but the water content of the blood again rapidly returns to normal as soon as the fluid is administered.

Muscular movement also modifies the passage of fluid through the capillary wall in that blood loses fluid very rapidly as it passes through active muscle and the flow of lymph from the region is increased many fold. During rest, loss of fluid from the blood ceases and lymph flow diminishes. Changes in position affect the movement of fluid from the blood to the tissues; quiet standing diminishes blood volume and elevates the concentration of the plasma proteins, because high intravascular pressure in the dependent lower extremities produces greater filtration and accumulation of fluid in the extravascular spaces of the legs. In the recumbent position this extravascular fluid is reabsorbed and blood volume returns to the earlier level. Under physiological conditions, therefore, fluid is moving at varying rates, at one moment inward, at another outward, through an extensive and highly permeable system of capillary walls. Nevertheless, gross variations in blood volume and in the volume of tissue fluid are avoided.

To explain the equilibrium existing between blood and tissue fluid under these diverse conditions, the most attractive hypothesis, and the one for which there is most evidence, is that advanced by Starling.⁷ The essential parts of this hypothesis can be summarized under four heads. (a) The blood flows through the capillary network under a pressure gradient, which if unopposed, filters fluid from the blood plasma through the capillary wall into the tissue spaces. (b) The capillary wall, though quite permeable to water, salts and simple organic compounds, is in most tissues relatively impermeable to the plasma proteins. (c) Those substances (such as salts, urea, creatinine, glucose, etc.) which pass easily through the capillary wall and are present in approximately equal concentration in blood plasma and tissue fluids, cannot exert a permanent osmotic pressure across the capillary wall and should not, therefore, affect the distribution of fluid, except temporarily. (d) The plasma proteins, by reason of their greater molecular dimensions, are retained by the capillary wall and thus develop a small, but physiologically important, colloid osmotic (or oncotic) pressure which, if unopposed, leads to absorption of fluid from the tissue spaces.

Starling postulated that the constancy of blood volume and of tissue fluid volume depends primarily upon the balance between capillary blood pressure and the colloid osmotic pressure of the plasma proteins, acting in association with a capillary wall which is impermeable to protein. In those areas where capillary pressure exceeds the colloid osmotic pressure of the blood, fluid should be filtered from the blood into the tissue spaces. In other areas where capillary pressure falls below the colloid osmotic pressure of the blood, fluid should be absorbed from the tissue spaces into the circulating blood.

This concept, in which physical forces are the prime agents controlling the movement of fluid through the capillary wall, can be applied only if the endothelium of the capillary network acts like an inert membrane. From the morphological point of view it is not likely that a membrane having the thinness⁸ and the structural

simplicity of vascular endothelium could have a secreting function. The available evidence led Krogh⁸ to state, "when I review all the facts that have come to my notice, I have no hesitation in saying that there is no trustworthy evidence of the capillary having any power of hindering or favoring the passage by diffusion of all kinds of crystalloids through the endothelium."

This view is supported by recent studies of the concentrations of electrolytes and simple organic substances in blood serum or plasma and in extravascular fluid, such as edema fluid. It has been shown also that the electrolyte concentrations observed when the capillary wall separates plasma and edema fluid are identical with those observed when the same fluids are permitted to come into equilibrium across a collodion membrane which is permeable to water and salts but impermeable to protein. It has been concluded that the normal living capillary wall does not act differently from a collodion membrane in this respect. This does not mean, however, that the concentrations of electrolytes are absolutely identical on the two sides of the capillary wall. The circulating plasma contains a considerable amount of protein, whereas the extravascular fluid contains less protein. Most of the small differences between electrolyte concentrations on the two sides of the capillary wall, or on the two sides of a collodion membrane, have been shown to depend upon differences in the protein content of the two fluids in that the observed concentrations are in general accord with the Gibbs-Donnan equilibrium. Certain additional minor discrepancies observed in the living organism, and not wholly explained by the Gibbs-Donnan equation, are probably due to as yet undefined modification of activity coefficients by the complex mixture of substances found in blood plasma or serum. In any case, the capillary wall cannot be responsible for these discrepancies because they persist when the same two fluids are separated merely by a collodion membrane. The non-electrolytes so far studied are found in approximately equal concentrations on the two sides of the living capillary membrane, or of the collodion membrane, as soon as true equilibrium has been reached.

All available evidence indicates that the capillary wall can be regarded as an ultrafilter comparable to an artificial membrane which is impermeable to protein. As Starling suggests, it follows that the osmotic pressure of the proteins must tend to absorb water from the tissue spaces, and that this absorbing force cannot be balanced by any other force than capillary blood pressure. Since this membrane has the physical characteristics of an inert (in the sense of non-secreting) membrane which is permeable to water and crystalloids, but relatively impermeable to plasma proteins, it is obligatory to regard physical forces as important factors in the movement of fluid through the capillary wall. It is also necessary to examine critically so-called "changes in capillary permeability" in which these physical forces have not been carefully controlled. The important physical factors to be considered are (1) capillary blood pressure, (2) the colloid osmotic pressure of the blood, (3) the degree to which the capillary wall is impermeable to proteins under normal conditions and after injury, and (4) the role played by tissue pressure and by the lymphatic vessels.

(b) **Capillary blood pressure.** Capillary blood pressure was originally measured by numerous modifications of the "indirect" technique in which, by means of a capsule or other device, external pressure was imposed upon cutaneous or more deeply placed capillaries to determine that pressure which modified skin color or interfered with the flow of blood through the vessels while they were being observed under a microscope. The spread of the observed values, the arbitrary nature of the criteria adopted to indicate balance between the external and internal pressure, and the lack of agreement between results obtained by different methods indicated that more exact determinations were necessary. This was finally accomplished by the introduction into individual capillaries of minute glass pipettes or needles having a diameter of four to ten microns and filled throughout with physiological salt solu-

tion.⁴ These micropipettes were connected to an apparatus to measure the pressure required to balance directly the intravascular pressure. These determinations have shown, in accordance with the Starling hypothesis and with theoretical considerations, that some of the peripheral resistance to blood flow is situated in the capillaries. The blood as it flows through the vascular system sustains little drop in pressure until the minute arterioles are reached, in which the drop in blood pressure amounts to approximately 70 per cent of the total. The capillaries account for approximately 30 per cent of the peripheral resistance and the gradient of blood pressure penetrates into the capillary network proportionately.

Average pressure in the arteriolar capillaries in four species, including man, rat, guinea pig and frog, was shown to be greater than the colloid osmotic pressure of the blood, while the average pressure in the venous capillaries was less than the colloid osmotic pressure of the blood. Under average conditions the relationship between capillary blood pressure and the colloid osmotic pressure of the blood indicates that fluid is filtered from the blood during its passage through the arteriolar portion of the capillary network, while absorption takes place in the venous portion of the capillary network. Though this represents the average condition, fluid movement in individual capillaries will diverge widely from the average in accordance with changes in capillary pressure, diameter and flow.

It has been mentioned that capillary blood pressure is an extremely variable figure, changing in the same capillary from moment to moment and differing widely even in adjacent capillaries connected to the same arteriole. Arterial and arteriolar constriction increases the peripheral resistance and capillary pressure becomes lower throughout the affected area, irrespective of the diameters of the capillaries themselves. Pulse pressure decreases and a lower capillary blood pressure favors absorption of fluid. Dilatation of the arterioles, on the contrary, shifts the peripheral fall of blood pressure toward the capillary network, usually elevates capillary pressure, increases the pulse pressure in the capillary vessels and increases the filtration of fluids. Any rise of venous pressure elevates capillary blood pressure, as does also the depression of tissues below heart level owing, in the latter instance, to the hydrostatic pressure of the blood in the vertically placed veins. Since blood pressure in an entire capillary, or even in a whole network, may be at one moment far above, and at another far below, the colloid osmotic pressure of the blood, massive filtration or massive reabsorption respectively may be observed in large tissue areas. With average resting circulation, however, filtration and absorption are roughly in balance.

The micro-injection technique has made it possible also to measure the effect of capillary blood pressure on fluid movement through the walls of single capillaries. Whenever, in a given capillary, the hydrostatic pressure is greater than the colloid osmotic pressure of the blood, the volume of plasma within the observed vessel becomes less as fluid is filtered from the blood through the capillary wall into the tissue spaces. On the contrary, in those capillaries in which blood pressure is lower than the colloid osmotic pressure of the blood, fluid moves in the reverse direction and absorption is indicated by increase in the volume of the plasma in the observed capillary. When capillary blood pressure is equal to the colloid osmotic pressure of the plasma proteins, fluid moves neither inward nor outward. Above and below this point the rate of fluid movement is directly proportional to the difference between these two forces. From these relationships the permeability of the capillary wall was calculated.

In the human forearm, when capillary blood pressure is raised by congesting the veins by known pressures, the accumulation of fluid in the extravascular spaces is directly proportional to the hydrostatic pressure exerted on the blood as it passes through the capillary network. This filtration can be measured either by increase in arm volume or by concentration of the cells produced by loss of fluid from the blood

plasma. Increasing venous pressure by 1 cm of water increases the filtration of fluid by 0.0023 cc per minute per 100 cc of forearm tissue.

In summary, the movement of fluid from blood to tissue spaces varies considerably with circulatory adjustments and particularly with capillary blood pressure. Active hyperemia and high capillary blood pressure increase the filtration of fluid. Elevating venous pressure is always associated with increased filtration, the rate of filtration being proportional, within certain limits, to venous pressure and capillary blood pressure. Low capillary blood pressure leads to absorption of fluid.

(c) **The colloid osmotic pressure of the blood.**⁹ Starling, in 1896, was the first to measure the magnitude of the colloid osmotic pressure produced when the plasma was enclosed within a membrane which was impermeable to protein and at the same time permeable to water and dissolved salts. In man the most recent figures indicate that the colloid osmotic pressure of the plasma proteins lies between 24 and 26 mm Hg, while average blood pressure is 32 mm Hg in the arteriolar portion of the capillary network and 12 mm Hg in the venous capillaries. In lower animals the colloid osmotic pressure of the blood is less, but capillary blood pressure is also correspondingly lower. This balance between colloid osmotic pressure and capillary blood pressure offers presumptive evidence that the plasma proteins are an important factor in the control of fluid movement.

The association of a low plasma protein percentage, and therefore a low colloid osmotic pressure of the blood, with some but not all forms of edema in man has been well established, particularly for certain stages of renal disease and in the edema of malnutrition or starvation. Edema of this particular type has, in fact, been produced in animals by reducing the colloid osmotic pressure of the blood by removing the plasma proteins and returning the red cells suspended in salt solution. Conversely, the addition of relatively large quantities of serum to salt solution with which a surviving limb is being perfused will delay, though not prevent, the appearance of edema which always follows the perfusion of simple salt solutions. To prevent edema of a perfused tissue indefinitely it is necessary also to assure adequate oxygenation of the perfused extremity for reasons that will be mentioned below. In the treatment of one type of hypoproteinemic edema a colloidal polysaccharide, acacia, has been used with some success in suitable instances. This substance acts merely by increasing temporarily the colloid osmotic pressure of the blood and thereby blood volume, so that diuresis is induced.

The effect of changing the colloid osmotic pressure of the blood can be compared quantitatively with that of changing venous pressure. Unit rise (1 cm of water) of venous pressure increases filtration through the capillary network of the human forearm by between 0.0023 and 0.0033 cc per minute per 100 cc of forearm. Conversely, a unit rise (1 cm of water) of colloid osmotic pressure diminishes filtration by 0.0027 to 0.0045 cc per minute per 100 cc of forearm.

In summary, available evidence, direct and indirect, indicates that the colloid osmotic pressure of the blood tends to retain fluid within the vascular system and acts quantitatively in opposition to capillary pressure. In accord with the view that the capillary wall is an inert (*i.e.*, non-secreting) membrane, the effects of capillary pressure and colloid osmotic pressure are opposite in sign but have the same order of magnitude. The sustained balance between these two forces will depend, of course, upon the efficiency with which the capillary wall prevents the passage of the plasma proteins.

(d) **Impermeability of the capillary wall to the plasma proteins.** The permeability of the capillary wall to protein could be defined easily and exactly if a true capillary filtrate could be obtained and analyzed for comparison with blood plasma. The collection and analysis of blood plasma offers no difficulties, but samples of normal capillary filtrate have not so far been obtainable because of the minute volume of this filtrate under normal conditions. Information concerning the permeabil-

ity of the capillary wall has necessarily been obtained chiefly by indirect methods. For this reason the three fluids upon which measurements have been made are (a) blood plasma, (b) the tissue fluid bathing the external surface of the capillary, and (c) lymph collected from small or large lymphatic ducts.

Tissue fluid consists of the original capillary filtrate mixed more or less with capillary filtrate which has been modified by partial reabsorption of fluid. Under these conditions any protein present in the original capillary filtrate would not be reabsorbed, and the resulting mixed tissue fluid may contain much more protein than was present originally in the pure filtrate.

Normally, because of active reabsorption, the volume of tissue fluid is also too small to permit collection of samples. In the edema of advanced nephrosis and malnutrition, the colloid osmotic pressure of the blood is usually much lower than capillary blood pressure. Reabsorption is then impossible and tissue fluid accumulates in the tissue spaces in large amounts. The composition of this fluid should approach that of the original capillary filtrate because reabsorption is minimal. The protein content of edema fluids, of widely differing pathogenesis, ranges from approximately 0.04 to 1.00 per cent. Very frequently edema fluids of mechanical origin contain less than 0.25 per cent protein, and when this figure is compared with the plasma protein percentage in the same patients, it appears that the capillary wall can under suitable conditions retain 95 per cent or more of the blood protein. The same conclusion is reached when the protein content of blood is compared before and after it has passed through capillaries subjected to venous congestion in order that reabsorption may be eliminated. According to this indirect method the capillary filtrate contains an average of 0.3 per cent protein, again indicating retention of approximately 95 per cent of the blood protein if anoxemia is avoided.

Analyses of lymph offer a third source of information on this point, but interpretation of results is slightly more difficult because the protein content of lymph varies from 0.2 to 4.7 per cent, depending upon the conditions under which it is collected. Lymph, like tissue fluid, contains (a) original capillary filtrate plus (b) the protein from any capillary filtrate of which the fluid and salts have been reabsorbed. Therefore, unless lymph is collected under conditions arranged to exclude absorption by the venous capillaries, the protein content will be higher than the original filtrate. The composition of lymph may furthermore be affected by its passage along the lymphatic channels or through lymph glands.

According to Drinker and Field,¹ lymph flow from a resting tissue is so slow that samples must be obtained by massage, and then contain as much as 4.7 per cent protein. It is likely that reabsorption of fluid is very active under these conditions. Contraction of the muscles of a limb increases the rate at which lymph flows along the lymphatics and diminishes the protein content to between 0.5 and 1.5 per cent. Red cells may also be found in this lymph. If the effects of exercise are avoided and at the same time reabsorption is excluded by raising venous pressure in the resting extremity, lymph flows more rapidly and simultaneously the protein content drops to as low as 0.2 per cent. Under these rigid conditions lymph probably reflects accurately the composition of the original capillary filtrate. If this interpretation is correct, indirect studies by 3 methods indicate that while the capillaries are not absolutely impermeable to plasma protein they nevertheless retain all but about 5 per cent of the protein in the circulating blood.

The fact that small amounts of protein are found in edema fluid and in lymph obtained during slight venous congestion invites inquiry into the manner in which protein leaks through the capillary wall. Protein might pass in very low concentration through the entire endothelial surface, or unmodified plasma might leak through a few capillaries which are abnormally permeable owing to trauma, or to a natural process of ageing. If the first possibility were correct, lymph would probably contain more albumin than globulin, because of the smaller molecular size of the albumin

fraction of the plasma proteins. If the second condition existed, the albumin-globulin ratio of lymph would tend to resemble that of blood. Examination of the albumin-globulin ratios of lymph and edema fluid are unfortunately not uniform enough to indicate the size of the pores through which protein passes. In most instances the albumin concentration is disproportionately high, indicating the presence of many small pores, but in other instances the ratio is practically that observed in the circulating blood.

The statements made so far apply to the capillaries of the extremities. In other tissues, particularly the intestines and liver, greater permeability is observed and lymph from these areas, even when reabsorption is avoided, contains from 3 to 4 per cent protein. Also it is only while the capillary wall is normal that it remains relatively impermeable to protein. Injury by chemical substances, heat or inflammation increases capillary permeability conspicuously. Under these conditions the capillary filtrate, edema fluid and lymph may contain almost as much protein as found in blood plasma. While the colloid osmotic pressure of the plasma, as measured *in vitro* across a protein-tight membrane, is normal, yet in the injured capillaries the effective colloid osmotic pressure is reduced in proportion to the leakage of protein. The ability of the plasma proteins to retain fluid in the affected capillaries is more or less diminished, filtration increases, and edema results.

In summary, the physical factors involved in the movement of fluid and dissolved substances through the vascular endothelium are so complex that changes in capillary permeability should be described only after careful control of physical forces known to influence the movement of substances through an inert membrane. Analyses of edema fluid, blood and lymph indicate that the capillary wall is relatively, but not absolutely, impermeable to protein. In the extremities the capillary endothelium normally retains at least 95 per cent of the total plasma protein. In some regions, however, permeability to protein is greater than this. Severe injury of any capillary network increases the permeability to protein so that all the plasma proteins pass freely, and filtration is thereby increased.

(e) **Diffusion and the permeability of the capillary wall to electrolytes.** The exchange of highly diffusible solutes to which the capillary wall is permeable need not follow the current of water during either filtration or absorption. When hypertonic solutions of electrolytes are introduced intravenously the electrolyte diffuses through the capillary wall toward the tissue spaces even while fluid is moving toward the blood. On account of the time required for the diffusion of electrolytes, fluid movement through the capillary wall is modified temporarily. This effect is transient and disappears when the concentration of electrolytes is once more equal inside and outside the capillary wall. The time required to attain equilibrium after the injection of hypotonic or hypertonic solutions depends upon the rapidity with which the substance diffuses through the capillary wall. According to Keys,² the approximate rates of diffusion across the capillary wall in man seem to be: $\text{H}_2\text{O} > \text{urea} > \text{K}^+, \text{Na}^+, \text{Cl}^-, \text{NO}_3^- > \text{Ca}^{++}, \text{Mg}^{++}, \text{phosphate} > \text{glucose}, \text{SO}_4^{--}, \text{SCN}^- > \text{sucrose}$. This order is roughly similar to that observed for gelatin, Cellophane and collodion membranes. Diffusion is doubtless aided by a current of water moving in the same direction but whether diffusion can be hindered appreciably by fluid moving through the capillary wall in the opposite direction is not known, though from rough calculation this seems unlikely. The independence of fluid movement and the diffusion of electrolytes is perhaps best illustrated by the behavior of certain dyes which have been used extensively to investigate the resistance which the capillary wall offers to the passage of substances whose molecular size lies between those of plasma protein and crystalloids. The passage of dyes can be followed easily since they are usually visible in low concentration. Interpretation of results, on the other hand, is often difficult owing to complicating factors such as electrical charge, selective staining, adsorption, toxicity, decolorization or deposition in the tissues.

This subject of diffusion of dyes through the capillary wall studied sporadically for decades, was investigated in considerable detail by Rous and his co-workers,⁶ who injected acid vital dyes intravenously and then studied the rate and intensity of staining of tissues about the capillaries and veins. They found that highly diffusible dyes escape so rapidly from the capillaries of mammalian muscle that the tissue surrounding the arterial end of the capillary is colored even before the venous end is reached by the dye-stained blood. Less diffusible dyes emerge all along the muscle capillaries, but in greater amount toward the venous end. Poorly diffusible dyes at first fail to appear outside the arteriolar portion of the capillary network but escape in increasing amount in the venous portion. Eventually in all cases diffusion causes the tissue to be evenly colored.

The preferential passage of poorly diffusible dyes through the walls of the venous capillaries and venules is but little affected by the changes of circulation and fluid movement which accompany muscular activity, plethora, severe hemorrhage, nerve section, shock, dehydration and injections of epinephrine and pituitrin. The independence between fluid movement and this diffusion is indicated further by the fact that capillary pressure can be reduced almost to zero and still dyes pass through the endothelium rapidly. Rous and his co-workers developed the hypothesis that the endothelium of the capillaries serving certain organs is relatively impermeable near the arterioles and becomes increasingly permeable as the venules and veins are approached. This might at first seem to invalidate the Starling hypothesis.

It is known, however, that plasma proteins pass through the vascular walls, including those of the venous capillaries and venules, only in small concentration under normal conditions. Therefore this gradient of permeability, which has so far been demonstrated only by dyes, does not affect the relation which fluid movement bears to the balance between capillary pressure and the colloid osmotic pressure of the plasma proteins, except possibly to hasten absorption and expedite the development of a state of equilibrium. These dye studies do indicate that gradients of permeability tend to equalize rapidly the distribution of nutrient materials of moderate molecular size even though they cannot appreciably influence the final equilibrium between the fluid in blood plasma and tissue fluid.

(f) **Tissue pressure and the movement of fluid through the capillary wall.** The pressure under which blood flows through the capillary network is only one part of the balance between the hydrostatic pressures inside and outside the capillary wall. If the fluid filtered by an excess of capillary pressure over colloid osmotic pressure passed into a space which could expand easily without distention, a high capillary pressure should produce filtration indefinitely at a constant rate. It is generally agreed, however, that this is not the case. In the tissues, and to a lesser extent in the serous cavities, the space available for accommodating extravascular fluid is limited. As fluid accumulates outside the capillaries, the tissue elements must be separated. Further filtration of fluid is then opposed by the pressure required to distort the tissues. If capillary pressure is elevated in an extremity by congesting the veins, the filtration rate is greatest during the first few minutes and then decreases rapidly during the first thirty minutes of congestion. At the end of thirty minutes, venous pressure and capillary blood pressure remaining the same, the rate of filtration is usually less than one quarter that observed during the first five or ten minutes. When sufficient fluid has accumulated in the tissue spaces low venous pressures will fail to produce further filtration.

Obviously the development of this tissue pressure tends to prevent edema in the dependent tissues of the human being where venous pressure for brief periods will often be much greater than the colloid osmotic pressure of the plasma proteins. It must be remembered, however, that whatever may be the importance of tissue pressure in limiting undue filtration under ordinary conditions, the mere existence of edema in disease shows in itself that the power of the tissues to resist accumulation

of tissue fluid is limited. If a tendency toward edema formation exists for a long time the tissues gradually give way. Their elasticity delays, but cannot prevent, the appearance of edema. It is a common observation that certain forms of edema appear first in the loose tissues of the orbit and face, but the mere looseness of these tissues is never the primary cause for the appearance of the edema. When filtration tends to exceed absorption over long periods of time, the less resistant looser tissues merely show pitting edema before the more compactly constructed tissues do.

Interchange of Gases

Available evidence indicates that the required interchange of gases between blood and tissue cells can be accomplished by diffusion both in rest and during exercise. This is possible, however, only because during activity of tissue the number of open capillaries increases conspicuously and mean blood flow increases in proportion. In a cross section of resting muscle only a few of the available capillaries are open, while the great majority are constricted. For example, Krogh³ stated that in resting muscle the open capillaries, though equally spaced, were as few as 5 per sq mm, whereas after exercise the corresponding muscle of the other leg contained 195 capillaries per sq mm—a forty-fold increase. The distance between open capillaries in resting muscle is therefore great, but with exercise the larger number of open capillaries reduces the number of muscle fibers supplied by each vessel.

Oxygen diffuses through animal tissues at rates between $\frac{1}{2}$ and $\frac{1}{3}$ as fast as those observed in water, but the diffusion constant increases with rising temperature about one per cent per degree centigrade. If each capillary be supposed to supply oxygen independently of all others to the cylinder of tissue surrounding it, the difference in oxygen pressure between the inside of the capillary wall and the outermost border of this cylinder will be proportional to the oxygen consumption and inversely proportional to the diffusion rate. Knowing the radius of the capillary, the radius of the cylinder of tissue it supplies, and the oxygen tension of venous blood, it is possible to estimate roughly whether or not simple diffusion is quantitatively sufficient to cover the oxygen requirements of muscle during exercise.

In resting muscle, with very few capillaries open, these calculations³ indicate that slight oxygen lack may exist in those parts of the muscle which are most distant from an open capillary. Usually, however, the number of open capillaries, though small, is sufficient to maintain an adequate oxygen tension everywhere. After massage, and particularly during work, opening of many previously closed capillaries reduces the radius of the cylinder of tissue to be supplied by each vessel to such an extent that the oxygen pressure in muscle becomes practically equal to that of the venous blood, and the greater utilization of oxygen is matched by a greater supply. As a matter of fact the number of capillaries opened by exercise, according to these estimates, is somewhat greater than that required for oxygen supply alone.

The diffusion constant for carbon dioxide is much higher than that for oxygen and it follows that this increased capillary bed will also provide for efficient elimination of carbon dioxide by simple diffusion into the capillary blood. Because the number of open capillaries is determined by the dilating effect of the metabolic products arising directly from tissue activity it is clear that the richness of local circulation is always suited to the metabolic needs of the immediately adjacent tissues in rest and during activity. By this means the independent contraction or relaxation of the capillaries, in association with like changes in arteriolar tone permits simple diffusion to provide both oxygen supply and carbon dioxide removal within a wide range of activity.

The Capillary Circulation In Special Conditions

(a) **Effects of heat and cold.** Though fluid movement is conspicuously modified by heat or cold there is no direct evidence yet to show that these changes are due to

any modification of capillary permeability per se, except when the change in temperature is great enough to injure the endothelium. Slight changes in capillary permeability due to variations in temperature are by no means ruled out, but even if present they would have little effect on the concurrent processes of filtration and reabsorption because, if permeability to protein remains constant, more rapid filtration in one area would be balanced by more rapid reabsorption elsewhere. Only if capillary permeability is increased to the point where protein passes with ease, will absorption cease. Thus excessive heat injures the capillary wall and produces edema, but this is the usual effect of tissue damage and not a specific effect of temperature.

It is common knowledge that the digits swell during warm weather and shrink during cold weather. This change in volume is partly due to the amount of blood in the vessels, though the rate of change is too slow to be explained satisfactorily on this basis alone. Local heat also dilates the superficial vessels and blood flow is much increased. Average capillary pressure in the skin of the finger under normal conditions amounts to 32 mm Hg in the arteriolar limb and 12 mm in the venous limb. When skin temperature at the tip of the digit is elevated to forty-two degrees centigrade capillary pressure rises to sixty and to forty five millimeters in the arteriolar and the venous limbs respectively. The excess of capillary blood pressure over the colloid osmotic pressure of the blood then leads to filtration of fluid which accumulates temporarily in the tissue spaces but eventually passes on into the lymphatic vessels. In the distal phalanges, however, there are many arteriovenous anastomoses which open widely whenever the tissues are heated or whenever vasoconstrictor tone is reduced. It is possible that the reactions of the fingertip are not quite characteristic of those elsewhere, and this difference may offer an explanation for the observation that heat is more apt to produce swelling in the distal portions of the extremities than in the proximal tissues. Local heat also increases the total filtering area available by dilating capillaries previously closed or only partially open; this factor would tend to increase the rate of filtration at any given venous pressure. It is impossible to estimate the relative importance of these two factors from the data at present available.

Plethysmographic studies indicate that as the temperature of an extremity is increased, a given venous pressure produces greater filtration in the warm forearm than in the cool forearm. At 44° C fluid accumulates twice as rapidly at a given venous pressure than is the case at a temperature of 15° C. At temperatures below 15° C, as shown by Lewis,⁵ the initial constriction of the minute vessels gives way to a reactive dilatation which is stimulated by injury and the secondary release of vasodilator substances, chiefly a substance similar to histamine. In fact, excessive cooling can produce marked vasodilatation, rise in capillary pressure, edema and blistering just as burning heat does. The blister fluid obtained from such excessively cooled or heated areas contains protein in concentrations approaching that of blood, indicating gross endothelial damage. When excessive heat leads to the formation of a blister, of which the burn is characteristic, the extravascular fluid is not only rich in protein but contains additional substances produced whenever tissues are injured. The blister fluid, when injected beneath normal skin, produces there both vascular dilatation and increased capillary permeability, owing to these contained histamine-like substances.

Other investigations indicate that heat increases the rate at which dyes pass through the capillary wall but the staining of the tissues does not become maximally rapid or uniform until the capillary wall is damaged. Also, injury by excessive heat increases lymph flow and the pressure in the lymphatic vessels may reach 120 cm of water. The protein content of such lymph also approaches that of blood owing to gross endothelial injury.

The effect of temperature on filtration is particularly interesting with regard to

the appearance, or the accentuation, of certain forms of edema in response to climatic changes. Frequently patients with mild edema complain that the swelling of the lower extremities is greater during warm weather than during cold. Physicians in tropical countries describe two types of this so-called "heat edema." The milder form is extremely common all over the tropics; Europeans on their way to the East frequently develop it when their ship reaches the southern portion of the Red Sea and Aden. The feet and legs swell slightly and pitting edema occurs without any evidence of renal or cardiac abnormality. Heat edema in more severe form was observed by Castellani in Europe and America during a heat wave. The edema comes on suddenly, lasts as long as the high environmental temperature persists and then disappears.

In a warm environment the cutaneous vessels of the upper and lower extremities dilate in order to promote the loss of heat. During such vasodilatation the total area of capillary wall available for filtration in the extremities must be increased. In the standing position venous pressure in the lower extremities reaches very high levels due to the hydrostatic pressure of the column of venous blood. With such venous pressure the greater filtering area favors excessive filtration of fluid. Heat edemas may therefore be at least partially due to physical effects similar to those exerted by local heat on the filtration of fluids through the normal capillary wall.

In summary, the effects of heat on fluid movement through the capillary wall can be explained satisfactorily on the basis of (a) capillary dilatation which increases the area available for fluid movement; (b) rise in capillary blood pressure which favors filtration; and finally (c) injury by excessive heat which, like other harmful agents, increases capillary permeability to colloids and consequently lowers the effective osmotic pressure of the plasma proteins. Prolonged and excessive cold can produce injury of the same degree as illustrated by frostbite. The effect of mild changes in temperature on the permeability of the capillary wall to fluid alone has not been ruled out but, other factors remaining constant, such change cannot be expected to influence conspicuously the balance between blood and tissue fluid.

(b) **Capillary pressure and permeability in relation to tissue function.** Secretory activity of glands and contraction of muscles are accompanied by a conspicuous increase of blood flow through the active tissues. Even temporary ischemia of the tissues, for example by a tourniquet, produces, after blood flow returns, a reactive hyperemia in response to the accumulation of metabolites which with normal circulation would have been carried away as soon as they were produced. The number of open capillaries in exercising muscle is, as mentioned previously, much greater than in resting muscles and the surface available for filtration is proportionately increased. Arteriolar dilatation and the opening of previously closed capillaries are generally ascribed to the direct action of metabolic products. While there is not complete agreement concerning the specific metabolic product which produces vasodilatation, the relation between tissue activity and conspicuous hyperemia is not questioned.

Many studies have shown also that tissue activity is accompanied by a shift in the equilibrium between the circulating blood and tissue fluid. As mentioned above, lymph can be obtained only with difficulty from resting muscle but it flows freely during and after a series of contractions, indicating that the filtration of fluid from the blood circulating through the exercised muscle is greatly increased. Physiological activity also increases the flow of lymph from the salivary glands and from the kidney.

Direct measurements have shown that capillary blood pressure rises following contraction of muscle. In resting frog's muscle average arteriolar capillary pressure is 14.9 cm of water while average venous capillary pressure is 9.5 cm; during the hyperemia which follows tetanus of muscle average arteriolar capillary pressure is 20.1 cm and average venous capillary pressure 16 cm without significant change in

either arterial or venous pressure. The rate of blood flow and pulse pressure in the capillary network are increased conspicuously during this period of hyperemia indicating general arteriolar and capillary dilatation.

Indirect determinations of filtration during muscular activity indicate, however, that the amount of fluid actually moving toward the muscles exceeds the possible filtration to be expected from a simple rise of capillary blood pressure. During muscular activity, when the blood is losing fluid at the rate of two cc per minute per hundred grams of functioning tissue, the rate of filtration is at least several times more rapid than it is in resting tissue under a venous pressure of 80 cm of water during rest and at a temperature of 44° C. This suggests that some other factor is concerned in producing the high rate of lymph flow characteristic of actively functioning tissues.

Because of the close relation between tissue activity and the rate of lymph flow it has been postulated that the osmotic pressure of metabolic products must change the equilibrium between blood and lymph. These metabolic products are diffusible and, by reason of their smaller molecular size, have an osmotic pressure greater than the parent substances from which they were derived. In agreement with this concept muscle after being completely fatigued by exercise, has an osmotic pressure greater than normal by about thirty per cent. This, of course, is an extreme condition following anaerobic contraction. The change in the vapor pressure of the circulating blood during exercise shows also that significant local changes in osmotic pressure in contracting muscle are quite within the range of possibility.

Since these osmotically active substances diffuse from muscle into the extravascular fluids, and then into blood, it is logical to suppose that fluid will be withdrawn from the blood stream until diffusion restores the osmotic equilibrium which usually obtains between the diffusible constituents of blood and tissue fluid. No change in capillary permeability is required, since this movement of fluid is due solely to temporary inequality of osmotic pressure inside and outside the capillary wall. When blood flow is kept constant, while the rate of metabolism is varied, the loss of fluid from the blood changes with metabolism. However, when metabolism is kept quite constant the loss of fluid from the blood changes in general with blood flow. It can be concluded that functional activity increases filtration (a) directly, by altering the osmotic properties of the tissue fluid, and (b) indirectly by inducing vasodilatation, increasing capillary pressure, and expanding the area available for filtration. This view at least explains the observation that lymph flow during muscular activity exceeds temporarily the filtration produced during rest by simple elevation of capillary blood pressure.

That the movement of fluid toward functioning tissues might conceivably be concerned also with increase in the permeability of the capillary wall itself is suggested by the relatively high protein content of lymph collected from dogs during walking. This lymph contains from 1.0 to 1.5 per cent protein. It is known that lack of oxygen increases the permeability of the capillary wall to protein. Moreover, in perfusion experiments oxygen supply must be adequate if edema is to be avoided. In active tissues the situation is more complicated because metabolic activity might modify endothelial permeability through lowering of oxygen tension, increase of carbon dioxide tension or by local increase in acidity. These three possibilities have been explored by the micro-injection technique and it has been concluded that after complete lack of oxygen for three minutes, fluid filters through the frog's capillary wall four times more rapidly than normal. At the same time the capillary wall, which is normally relatively impermeable to protein, permits protein to pass and the effective osmotic pressure of the plasma proteins is reduced to one-half normal.

The movement of fluid through the asphyxiated capillary wall is still directly proportional to the difference between capillary pressure and the effective osmotic pressure of the plasma proteins indicating that even under these conditions the

endothelium acts merely as a passive filter, though it is more permeable than normal. When blood flow is resumed after brief oxygen lack the capillary wall rapidly recovers its impermeability to protein and the rate of fluid movement also returns practically to normal. The effects of oxygen lack, if sufficiently brief in duration, are almost completely reversible but longer periods of asphyxia produce irreversible changes in permeability.

Similar exposure of the frog's mesentery to Ringer's fluid half saturated with carbon dioxide does not modify fluid movement, and complete saturation increases the rate of fluid movement very slightly; but in both cases the wall still remains normally impermeable to protein. Likewise, increasing the hydrogen ion concentration within physiological limits produces almost no change in fluid movement until, at a pH of 4.0, the characteristic effects of injury appear.

Though complete lack of oxygen increases capillary permeability, it is still doubtful whether the oxygen tension in functioning tissues with normal blood vessels ever becomes low enough to produce this change. Anoxemia would have to occur in spite of increased blood flow and the opening of many new capillaries which, according to Krogh,³ is so efficient that, theoretically, the oxygen tension through the entire exercising muscle is practically that of venous blood.

Lymph collected from contracting muscle ordinarily contains more red cells than are present in lymph collected from resting tissues. It has been suggested that these erythrocytes may escape through preformed stomata, probably within the cement substance, which open under increased pressure and close when pressure is reduced to normal. When muscle is strongly contracted groups of capillaries can be seen to be obviously distended, because the pressure exerted by contracted muscle fibers flattens the small venules draining the region under observation. With relaxation of muscle, blood will frequently spurt from such capillaries into the venules. Apparently any openings thus produced can appear and disappear without modifying the normal permeability of the capillary wall under ordinary conditions. Future work on the relation of capillary permeability to oxygen lack and to these temporary openings may explain some of the perplexing anomalies of fluid movement observed during tissue activity.

In summary, functional activity of the tissues produces hyperemia and with it a rise in capillary blood pressure. The increased flow of lymph which accompanies vigorous tissue activity is probably too great to be explained on the basis of a simple rise in capillary pressure or increase of filtering area. It is likely that osmotically active substances produced in the course of tissue metabolism are partially responsible for this copious and temporary filtration. Accumulation of carbon dioxide and changes in hydrogen ion concentration within physiological limits have little, if any, influence on capillary permeability, certainly not enough to modify the effective colloid osmotic pressure of the plasma proteins to any measurable extent. Lack of oxygen, if extreme, can produce a temporary increase of permeability which is great enough to permit protein to pass but it is doubtful whether anoxemia of this grade can be produced in active tissues with normal blood flow.

(c) **The effects of injury on capillary pressure and permeability.** The effectiveness with which the plasma proteins retain water within the capillaries depends upon the vitality of the endothelium. All forms of injury increase capillary permeability and reduce correspondingly the effective colloid osmotic pressure of the blood. Tissue damage therefore influences the movement of fluid through the capillary wall in a complex manner by reason of simultaneous changes in blood flow, capillary pressure and capillary permeability.

The injury that is produced when a single capillary is pierced by a micro-pipette is extremely slight, but nevertheless is often followed by clear increase in blood flow and capillary pressure. If a single capillary in the frog's mesentery be compressed

gently by means of a minute blunt glass rod the effect of local injury on the permeability of the endothelium becomes apparent at once. Colloidal dye solutions pass freely through such an injured area before they can be detected outside normal areas of endothelium in the same capillary. The colored fluid does not spurt from a single point as it should if the endothelium were mechanically ruptured, but filters out uniformly along the whole damaged section. India ink introduced intravenously flows past the normal section of capillary but the carbon particles accumulate in dense masses on the inner surface of the injured section. When a single capillary is severely injured blood corpuscles and ink are commingled in a solidly packed collection, indicating that endothelial permeability is maximally increased and that whole plasma has filtered through the damaged section of capillary wall.

Injury which, instead of being limited to a minute area, affects large portions of the peripheral vascular system, initiates a series of events which are fundamentally similar in their development irrespective of the agent used. Small amounts of harmful substances introduced intravenously, or applied to a tissue externally, produce simply vasodilatation, increased rate of blood flow and usually a rise of capillary blood pressure. More severe injury is followed by visible concentration of the red cells, slower flow, and finally complete stoppage of circulation due to complete loss of plasma through the damaged endothelium. This is true stasis and the solid cylinder of compressed red cells devoid of plasma, is the surest sign of increased capillary permeability. When injury reaches this stage proteins, colloidal dyes, and colloidal starch pass through the capillary wall rapidly, but India ink particles and red cells are retained quantitatively. On this account Krogh³ has placed the size of the pores in damaged endothelium between 5 and 200 millimicrons, whereas the pores of normal endothelium, according to Keys,² have diameters between 0.7 and 2.1 millimicrons. At a given capillary pressure fluid filters from 5 to 7 times more rapidly through an injured capillary wall than through a normal capillary wall. At the same time the endothelium becomes sticky so that leucocytes, erythrocytes, and platelets adhere to the damaged capillary wall.

While the increased transudation through the walls of injured capillaries is due chiefly to greater capillary permeability it is also influenced by capillary blood pressure. The rate at which blood plasma leaves the injured capillary is greater during cardiac systole when capillary pressure is high, than during diastole, when capillary pressure is slightly lower. If systemic blood pressure is very low stasis develops much more slowly. Conversely, stasis develops more rapidly in a capillary network with rapid blood flow and higher capillary blood pressure.

If the injury is great enough to produce immediate stasis edema rarely appears for the obvious reason that blood flow ceases in the injured area before sufficient fluid can pass out of the blood vessels to distend the tissues grossly. Milder grades of damage persisting over longer periods of time permit fluid to filter in sufficient amount to produce edema.

The histamine wheal illustrates very well the complex reactions which follow injury. If 1:1000 histamine is introduced into the skin by placing a droplet of the solution on the skin and then puncturing the skin with a fine needle through the droplet the so-called "triple response" develops. (a) In 20 seconds a small red spot develops around the puncture due to stasis in the minute vessels immediately affected. (b) This is followed in 1 to 2 minutes by a pink flare from 2 to 4 cm in diameter due to dilatation produced by a local nervous reflex mechanism (the axone reflex) in which vasodilator impulses relax the minute vessels. (c) In 2 to 3 minutes a wheal, or area of local edema, forms around and over the red spot, with a diameter of 2 to 3 mm. This local edema is due to leakage of plasma from the capillaries which have been made highly permeable by the histamine. The wheal fluid contains a large amount of protein. Lewis⁵ has presented detailed evidence to indicate that any form

of injury—thermal, chemical, mechanical, or physical—liberates from the tissues a histamine-like substance which is responsible for the circulatory changes in inflammation.

The inflammatory swellings seen in pathological conditions demonstrate in their early stages all of the reactions characteristic of local injury, but in later stages are complicated further by gross tissue destruction and liquefaction. There can be little doubt that the permeability of the capillary endothelium is increased in all types of inflammation because colloidal dyes pass more easily, and exudates in general contain protein in concentrations approaching that in blood plasma. Vasodilatation, increased blood flow, later sluggish blood flow and even stasis in isolated areas, with accompanying changes in capillary blood pressure are all found at some stage of inflammation. Even though the capillary wall is injured grossly, agents which reduce capillary blood pressure diminish filtration to some extent, while those which elevate capillary pressure increase the accumulation of edema fluid.

In summary, local injury initiates a complex response including vasodilatation, rise in capillary blood pressure, increased blood flow, increased endothelial permeability and, if injury is very severe, finally stasis and reduced blood flow. All forms of local or general edema produced by injury are due fundamentally to increased capillary permeability and resulting passage of proteins and fluid through the endothelium.

⁸ Structure may be a factor here, and mere morphological thinness is no positive criterion for secretion, which with some plant cells takes place through septa no thicker than endothelium, and appears also to take place through vacuolar membranes, *e.g.*, in the contractile vacuole of ameba. J. A.

⁹ The attraction of plasma for water ("plasma thirst") is opposed by the corresponding attraction of the tissues ("tissue thirst"); and the distribution of water is influenced by these interrelated factors, the intensities of which vary with the diffusion of metabolic products, *e.g.*, CO₂ which diffuses from tissues to blood (erythrocytes) while O₂ diffuses into tissues. (See J. Alexander, "Colloid Chemistry," 4th ed., D. Van Nostrand Co., 1937). A somewhat analogous situation exists in plants, where the "root pull" is opposed by the "back pull" of the soil. The percentage of water left in the soil when the plant can no longer protect itself against desiccation by taking up soil moisture, is known as the "wilting coefficient." Its value varies greatly with both plant and soil; thus, in the case of Kubanka wheat it is 2.59 for fine sand, 9.66 for fine sandy loam, and 16.3 for clay loam. (See J. Alexander, *lib. cit.*, p. 191). J. A.

EDITOR'S NOTE

In Vol. II of this series, Prof. Frank P. Underhill (pp. 723-730) pointed out that in the case of extensive burns, affecting over about one third of the body surface, death generally occurs because the viscosity of the blood becomes excessive, due to loss of water from the plasma to the tissues. "The systematic treatment of these burn cases consisted simply in the forcing of fluids, water by mouth when possible; when the patient could not cooperate because of unconsciousness, fluid was injected under the skin, directly into the blood, by rectum, etc. The quantity of fluid taken in varied from 4 to 8 liters daily. In a day or two on this treatment the blood concentration fell gradually and the patient's condition steadily improved." Prof. Underhill also points out that "burns" from "war gases" may have analogous effects.

Experimenting with mice subjected to standardized burns, Sanford M. Rosenthal (Public Health Repts., **58**, 513-522 (1943)) found that the mortality during the first 72 hours was significantly reduced by administration of sodium chloride solutions by mouth or intraperitoneally, isotonic solutions being better than hypertonic solutions. Intravenous injection was less effective. Potassium chloride caused an acceleration in the time of death, and when

administered with NaCl it antagonized the effects of the latter. Another factor to be considered was pointed out by H. Kabat and M. Levine (*Science*, 96, 476 (1942)), who found that in some cases speedy death may follow burns because of protein coagulation, leading to the formation of emboli.

Biochemical and Physiological Mechanisms in Inflammation *

VALY MENKIN, M.D.

Department of Pathology, Harvard University Medical School, Boston, Mass.

Inflammation may be broadly defined as the complex vascular, lymphatic and local tissue reaction elicited in higher animals by the presence of microorganisms or non-viable irritants. It represents a basic or elemental reaction to injury whereby the deleterious agent tends to be localized and ultimately destroyed. The phenomenon of inflammation as manifested in the vertebrate kingdom may properly be regarded as the physical basis of infectious processes. It may be considered as an immunological mechanism of definite significance. The inflammatory reaction irrespective of the irritant tends to develop along a uniform pattern. Foreign substances whether viable or non-viable in contact with normal tissue will induce the reaction, the intensity of which may vary from a barely visible hyperemia to an intense suppurative process.

The purpose of this review is to summarize the available evidence on the biochemical and physiological mechanisms involved in the development of the inflammatory reaction. The immunological implications of inflammation have already been considered in detail elsewhere (Menkin, 1938a, 1940a), and therefore this important aspect of the problem will in the present chapter be treated with brevity.

The orderly sequences in the development of the inflammatory reaction can be conveniently classified somewhat as follows:

1. The Vascular Capillaries in Inflammation. The inflammatory reaction is initiated by an alteration in the local fluid exchange. This is primarily referable to a basic disturbance in the local filtration equilibrium between the small vascular channels, the lymphatics and the so-called intercellular fluid.

The most satisfactory hypothesis that explains filtration between blood and tissue was first offered by Starling (1896). The concept was subsequently verified by the measurements of Landis (1926, 1927). In brief, this investigator concluded that the gradient of pressure along the course of the minute vessels favors filtration at the arteriolar portion of the capillary and reabsorption at its distal part. The rate of fluid passage appears to depend on the balance between the capillary pressure and the osmotic pressure † of the plasma proteins. These original conclusions were based on the assumption that the endothelial lining resembled an inert membrane and that it was essentially impermeable to the outward passage of proteins. This concept was modified by Drinker and his collaborators who demonstrated that the endothelial wall of capillaries was not wholly impermeable to the leakage of proteins. An appreciable concentration of proteins to be reckoned with was recovered from the lymph which thus reduced markedly the effective osmotic pressure of the plasma colloids (Churchill, Hakazawa, and Drinker, 1927; Drinker and Field, 1933).

In the last ten years the importance of the capillary filtration of Starling, revived

* These studies were aided in part by grants from the International Cancer Research Foundation, the Dazian Foundation for Medical Research and the Milton Fund of Harvard University.

† Also termed onkotic pressure. See H. Schade, Vol. II, p. 635, this series. J.A.

by Schade (1927) and verified by the ingenious measurements of Landis (1926, 1927) has been critically scrutinized in view of the findings of Rous and his collaborators (1930). These investigators injected intravenously some poorly diffusible dyes into frogs and into mammals (guinea pigs, rabbits and mice). The dye was observed to escape primarily from the distal part of the capillary and from the small venules, thus giving rise to a mounting gradient of permeability.

The gradient was observed to be independent of various factors, including hydrostatic pressure (McMaster, Hudack and Rous, 1932), osmotic pressure (Smith and Dick, 1932), nervous section, hemorrhage or cessation of circulation. Rous concluded that the permeability gradient was most likely referable to structural differentiation of the capillary wall rather than to any functional alteration. To Rous the mounting permeability gradient represents an adaptive mechanism for the equalization of opportunity in the distribution of diffusible nutrients to tissue. Through such a delicate regulatory mechanism a homeostatic state is effectively maintained in tissue, in accordance with Bernard's concept of the "milieu interne."

On the basis of his results, Rous cast some doubt on the validity of the Starling hypothesis as an adequate explanation of fluid exchange. Rous and Smith (1931) failed to confirm Landis' observations on the passage of trypan red (vital red HR) through the arterial part of the capillary wall in the frog mesentery. Landis (1934) insists that observations made with a relatively poorly diffusible dye, such as have been used by Rous and his collaborators should not be stressed too far in the evaluation of data pertaining to highly diffusible constituents of blood. Peters (1933, 1935) agrees that the Rous permeability gradient may be concerned in certain tissues with the equalizing of opportunities in distribution of nutrient material of large molecular dimensions. But according to this investigator, this fact in itself alters in no way the Starling-Landis hypothesis which is still considered a reasonable explanation for the local fluid exchange of water and electrolytes through the capillary wall.

The recent work of Zweifach (1940) in regard to the structure of the capillary wall and the factors at play in determining permeability under what is interpreted as approximating physiological conditions, is doubtless of distinct interest. According to this author, the capillary barrier is referable to an intercellular cement substance and also to an adsorbed layer of protein. The cement substance seems to be a calcium proteinate. In the opinion of this worker, the cellular components of the capillary wall seem relatively unimportant in determining permeability. Danielli (1940) has recently assembled the results of numerous experiments tending to show that edema formation seems to be associated with platelets. Serum, red cells or merely solutions containing platelet material reduce edema formation more than can be accounted for by the osmotic pressure of colloids. The view is advanced that the action of the platelets may be primarily mechanical, involving thus a blockage of the protein-permeable pores. The observations of these last two investigators may yet prove to be of distinct significance in clarifying our understanding of the nature of the capillary wall and of some of the factors capable of influencing filtration.

The introduction of a chemical or bacterial irritant into normal vertebrate tissue is followed by definite disturbances in the filtration equilibrium. There is local increase in the passage of plasma as evidenced by the edema which may develop fairly early. Both the capillary pressure and the mounting permeability gradients are so profoundly altered as to favor enhanced fluid accumulation in the affected tissue. The principal forces at play in promoting these changes may be listed as follows:

1. Increased capillary pressure accompanying local vasodilatation.
2. Increase in the actual number of functioning capillary channels.
3. Increase in capillary permeability. The initial constriction of the small vessels which is frequently encountered will not be discussed here owing to the lack of exact data on the mechanism and significance of this phenomenon.

Krogh (1922) assumed that the increased filtration through the capillary wall following the use of urethane was referable to the stretched endothelium of the dilated capillary. Landis (1927) demonstrated by intravascular injection of dyes that there was no measurable increase in permeability with dilatation of the capillaries. The passage of fluid seemed to be primarily referable to the level of intracapillary pressure. This investigator regards the effect of urethane as the result of direct injury to the endothelial lining accompanied by an increased capillary pressure.

The available data indicate that capillary dilatation in hyperemia or inflammation is accompanied by increased capillary pressure (Landis, 1931). This elevated pressure constitutes a definite factor that favors the outward passage of fluid. Landis concluded that the rise in capillary pressure in hyperemic conditions was referable to arteriolar dilatation. There was no indication in his experiments of any increased venous pressure to account for the augmentation in the intracapillary level. Hyperemia was induced, for instance, by placing a crystal of silver nitrate on the skin of the web of a frog. Within 1 to 3 minutes there was a rapid rise in capillary pressure which returned, as a rule, to the resting level within 7 to 20 minutes. The average rise in pressure varied between 19.5 cm of water to 16.5 cm depending on whether measurements were made in arteriolar or venous capillaries. Landis believes that this transient rise in pressure is referable to a stimulation of the axon reflex which causes arteriolar dilatation with accompanying increase in capillary pressure. It is obvious that an increase in pressure within capillaries would be significant in promoting filtration through the endothelial wall.

Probably an even more striking factor favoring increased seepage into the extracapillary spaces of an inflamed area is an actual change in the endothelial lining which increases its permeability or capacity for permitting the passage of fluids. Cohnheim called attention to this phenomenon about fifty years ago. Landis (1927) pointed out that capillaries injured by alcohol and mercuric chloride appear to be permeable to the plasma colloids and approximately seven times more permeable to fluids than is the normal capillary wall.

The extent of injury to the capillary wall can be demonstrated in the early phase of the inflammatory reaction by a variety of means. For instance, graphite particles that normally fail to pass through the endothelial membrane readily do so in the early stage of an acute inflammatory process (Menkin, 1931a). Another convenient method of demonstrating the alteration in the permeability of the endothelial wall in injury is by the use of intravenously injected dyes. Trypan blue and other dyes introduced into the circulating blood promptly accumulate in an inflamed area. The localization of vital dyes in areas of inflammation has been demonstrated by several investigators. MacCurdy and Evans (1912) pointed out that the normal brain and cord always remain free from dye injected intravenously but that areas of damage, such as softening or inflammation, become deeply stained. Bowman, Winternitz, and Evans (1912) found that trypan blue injected intravenously stains tubercles in experimental tuberculosis. Subsequently Winternitz and Hirshfelder (1913) demonstrated that this dye when injected intravenously in experimental lobar pneumonia stains the consolidated area of lung selectively. Lewis (1916) found that if the cornea of a rabbit is inoculated with a living culture of tubercle bacilli, a progressive lesion results characterized by an intense congestion of the conjunctiva. If the animal receives an intravenous injection of trypan red 24 hours or more after such inoculation, the fluid in the anterior chamber of the inoculated eye always becomes colored. Precisely similar results were obtained when abrin was administered in the conjunctiva as an inflammatory irritant. A number of years ago McClellan and Goodpasture (1923) showed that trypan blue accumulates in lesions of herpetic encephalitis in the rabbit's brain, the injured areas presenting a striking color against the quite unstained healthy brain tissue. Siengalewicz (1925) pointed out that general damage to the nervous tissue, such as poisoning with carbon monoxide

or with salvarsan, is followed by marked staining of the damaged areas by trypan blue. Ramsdell (1928) injected trypan blue into the veins of rabbits and guinea pigs previously treated with foreign serum and found that injection of the same serum into the skin of the ear immediately caused local infiltration of the dye into the adjacent tissue. She regarded the infiltration of the dye as an indicator of edematous changes resulting from toxic injury to the capillary endothelium.

Okuneff (1924) found that a thermal irritant favors the passage of vital stains from the blood stream into the area heated. Kusnetzowsky (1925) also observed that the local application to the skin of an irritant, such as heat or mustard oil, causes an accumulation of trypan blue in the inflamed area when the dye has previously been injected into the blood stream. Menkin (1929) demonstrated that trypan blue injected into the circulating blood enters the site of inflammation rapidly and is fixed there, so that the tissues are deeply stained. Furthermore, trypan blue injected directly into the site of inflammation in the subcutaneous tissue or in the peritoneal cavity is fixed in the inflamed area and fails to reach adequately the regional lymphatic nodes. This work clearly showed that there is not merely a rapid accumulation of the dye from the blood stream into an acutely inflamed area, but also that the dye is held in such an area and is unable to drain readily away through the regional lymphatics.

The accumulation in inflamed tissue of a dye that has been introduced into the blood stream is doubtless primarily the result of an increased permeability of the capillaries which is part of the inflammatory reaction. Menkin and Menkin (1930) were able to secure quantitative data by studying directly the change in the concentration of the dye in the blood stream both in the inflamed and in the normal mesentery of the frog. They found that, with the irritants employed, the permeability of the capillaries in the injured area was almost doubled.

Sufficient evidences have been adduced indicating that increased filtration in inflammation is primarily the result of an alteration in the permeability of the capillary wall. This, in turn, is reinforced to some extent by a transient and initial increased capillary pressure.

2. Mechanism of Increased Capillary Permeability in Inflammation. The precise mechanism involved in the initial augmentation of capillary permeability in injury is obviously of considerable importance for an adequate understanding of the subsequent sequences in the development of an inflammatory reaction. In 1923 Ebbecke postulated that a substance is formed by irritated epithelium which on diffusing to the cutis dilates the capillaries and smallest arterioles. Subsequently Lewis (1927) postulated the development of a type reaction primarily referable to a chemical H substance liberated from injured tissue. The H substance is presumably histamine or a substance having similar properties and therefore resembling it closely. According to Lewis and Grant (1924) the type reaction elicited by the cutaneous injection of histamine manifests itself in three ways: *a*, a local vasodilatation of capillaries, venules, and arterioles by direct action; *b*, a widespread dilatation of outlying arterioles resulting from a local reflex; and *c*, an increase in the permeability of the minute vessels by direct action. This type reaction leads to local edema of the skin.

The conclusions of Lewis and Grant (1924) appear to be based largely on an analogy of the type reaction obtained by histamine with that of a variety of other injurious agents. When more direct tests were performed on the effect of the skin wheal fluid on the contraction of the guinea-pig uterus, they were unable to obtain any evidence that histamine was liberated in larger quantities from injured tissue than was found in normal plasma.

Krogh (1929) accepts unreservedly the view first foreshadowed by the work of Ebbecke (1923), and later chiefly sponsored by Lewis, that under certain stimuli the tissue cells will liberate substances having a dilator effect on capillaries; but at the same time he finds it impossible to assume that in all cases the action is referable to a

single chemical H substance. For this reason Krogh postulates the possibility of two effective substances liberated from injured cells: a diffusible factor closely related to histamine, if not histamine itself; and an H colloid substance which is probably less diffusible. Rous and Gilding (1930) raise considerable doubt concerning the validity of a hypothesis which refers all local vasodilatation to the action of a single chemical substance liberated within tissues. They point out that the vascular contraction in Bier's spots prevails over the local reddening induced by mechanical injury, whereas it is without effect upon the local vasodilatation induced by cutaneous injection of histamine. More recently Goldschmidt and McGlone (1934) have studied the failure of a reactive hyperemia occurring with arrested circulation in an oxygen atmosphere. They have compared their findings with the histamine reaction in a similar oxygenated and isochemic environment. Their observations on the human forearm seem incompatible with the view that the vasodilatation responsible for reactive hyperemia is due to an H substance identical with histamine. By comparing the reactions of the dilated minute skin vessels to adrenaline puncture and to Bier's spots, Percival and Scott (1931) have been unable to conclude that the vascular reactions in exfoliative dermatitis, ultra-violet erythema, oil of mustard erythema, psoriasis, dermatitis venenata, and tinea corporis (ring-worm) were due to a histamine-like substance or histamine itself. That histamine is not always the active substance responsible for the increased capillary permeability in injury is indicated by the observations of Grant and Jones (1929) on the frog. This substance causes no dilatation of the frog's blood vessels either when applied locally or when given intravenously. They express the belief that in the frog the active substance is a base of the histidine-arginine fraction which is responsible for the vascular reaction to injury. The contention raised by Rous and Gilding has been reinvestigated by Wayne (1931) who arrives at the conclusion that the vascular reactions resulting from injury to the skin are due to a liberated substance, either histamine or some substance closely allied to it. This worker answers the objection of Rous and Gilding by maintaining that the vasoconstrictor effect of Bier's spots can overcome the slight local vasodilatation produced by histamine, provided the latter is introduced electrophoretically into the skin in a diffuse manner and in low concentrations. The vasoconstriction will, however, not prevail over a more intense local vasodilatation induced by greater concentrations of histamine. He therefore concludes that the vessels of the skin, under the influence of either histamine or the H substance liberated by injury, behave similarly towards Bier's spots when the two are distributed in a comparable way throughout the tissue spaces.

A study was undertaken by Menkin (1936a) in order to determine whether one or more substances could be obtained from inflammatory exudates which, when introduced into normal cutaneous tissue, would induce local vasodilatation and an increase in the permeability of the capillary wall. Furthermore, the properties of the active fractions which have been obtained from inflammatory exudates have been compared with histamine in an endeavor to test Lewis' hypothesis. In brief, the writer's observations indicate that a diffusible crystalline material capable of increasing capillary permeability is present in various types of inflammatory exudates. Its liberation and presence in exudates offers a reasonable explanation for the mechanism of increased permeability of small vessels in injured tissue. By appropriate tests this active principle has been shown to lack the properties characteristic of histamine (Menkin, 1936a, 1937, 1938b).

The evidence obtained by several authors indicates that histamine is present in exudates (Loos, 1931; Bier and Rocha e Silva, 1938; Menkin, 1938b, 1939a, b); but the primary importance of histamine in explaining the mechanism of increased capillary permeability in inflammation is now open to serious doubt. The finding by Feldberg and his associates (1937) that perfusion of the lung by snake venoms, staphylococcus toxin, or peptone, induces the liberation of proteins and of histamine

is no demonstration that the latter substance is primarily involved in the mechanism of enhancement of capillary permeability during injury. Countless substances are probably liberated from a site of inflammation, but whether many of these participate as important factors in directly determining increased capillary permeability is another matter. The case of histamine has not been satisfactorily proven. The permeability factor (termed leukotaxine) recovered from an exudate, described and isolated by Menkin (1936a, 1938a, b), displays none of the properties of histamine. Yet the purified permeability factor manifests identical reactions on the capillary wall as obtained by the untreated exudate. When histamine and the permeability factor were compared with regard to their respective properties, the following observations were made: (1) Upon intravenous injection of dye, the local staining pattern differed with each of these two substances. In dilution of 1:500,000 or 1:1,000,000 histamine may induce, as recently shown by Bier and Rocha e Silva (1938a), the accumulation of dye in the center of the area; but even in such dilution the pattern of staining is much lighter and over a larger area than is the case with exudate or the purified permeability factor. Furthermore, Bier has shown that the recovered amount of histamine in exudate induced by turpentine reaches a level of concentration ranging between 1:20,000 and 1:50,000. At such concentrations the pattern of staining induced by histamine is wholly different from that obtained by leukotaxine. Bier also reports that "inflammatory exudates of low histamine content are incapable of increasing capillary permeability in the treated cutaneous areas." The earlier studies of this investigator (1938a), cited above, have definitely pointed out that it is with low concentration of histamine that trypan blue accumulates from the circulating blood into a treated skin area. These facts, in themselves, would tend to invalidate the original claim that the permeability factor and histamine are identical. (2) In contrast to the usual effect elicited by histamine, the permeability factor failed to cause a contraction of the isolated intestine. (3) Following treatment with the permeability factor the intestinal segment exhibited no refractory state; the usual contractile effect elicited by histamine occurred. (4) Evidence was obtained of the antagonistic action of histamine to the active principle when mixed *in vitro* and then tested on the capillary wall. (5) The specific Zimmermann color reaction for histamine (1930) was negative when tested with the permeability factor. (6) A rapid chemotactic effect was induced by the permeability factor (leukotaxine); histamine apparently does not cause leukocytic migration. (7) The permeability factor failed to depress blood pressure in the cat in the manner characteristic of histamine (Menkin and Kadish, 1938). Recently Abramson and his collaborators (1938) have further confirmed by an iontophoretic method the earlier conclusions of the writer that histamine is probably not responsible for the production of hyperemic wheals.

The first method used by the writer to determine the effect of the permeability factor on the endothelial wall consisted of injecting the cell-free exudate intracutaneously in rabbits (1936a). This was almost immediately followed by an intravenous injection of trypan blue. The extent of accumulation of the dye in the treated cutaneous area served as a gauge of capillary permeability.

Bier and Rocha e Silva (1938b) have recently repeated the earlier studies of the writer on whole exudates and have confirmed his findings of a permeability and of a chemotactic factor in inflammatory exudates. They have, however, neglected to purify the exudates in order to obtain the relatively pure material capable *per se* of reproducing the increased capillary permeability and migration of polymorphonuclear leukocytes. On the basis of only meager evidence, they have concluded that the permeability factor (but not the chemotactic factor) is histamine. Their conclusions have been reached after extracting histamine from exudates, by the method of Barsoum and Gaddum (1935) in order to eliminate thus the presence of any depressing substances when the end-product is tested on the isolated strip of guinea pig

intestine. They admit, as the writer has pointed out above and also previously (1936a), that with the accumulation of trypan blue there is a difference in the staining pattern of tissue as elicited by histamine and by an inflammatory exudate. Yet these investigators assume without any evidence, that this is presumably referable to the loose combination of histamine with proteins or by adsorption of colloids. In brief, their observations on the contraction of the isolated intestine of the guinea pig simply indicate that histamine probably exists in exudates, and can by appropriate extraction, be demonstrated. This, as mentioned above, has been surmised and known.

The permeability factor (*i.e.*, leukotaxine) recovered and isolated from an exudate displays none of the specific properties of histamine. Yet leukotaxine is capable *per se* of reproducing the same type of reaction as the whole exudate. The mutual, non-specific properties of leukotaxine and histamine (*e.g.*, dialyzing property, etc.), listed by Rocha e Silva and Bier seem quite insignificant for the most part, inasmuch as they are true of numerous other unrelated substances. These investigators have failed to repeat the work on the chemical extraction of leukotaxine from exudate. They have worked solely with whole exudates. They have thus been unable to establish the fact that leukotaxine is histamine; whereas the writer has definitely demonstrated that leukotaxine has a great many physiological and chemical properties differing from those of histamine (Menkin, 1936a, 1938a, b, 1939a).

A single very important concrete evidence which nullifies the contention of these investigators is indicated by the following observation: A sample of leukotaxine, capable *per se* of actively inducing increased capillary permeability and leukocytic migration, is extracted for the presence of histamine by the method of Barsoum and Gaddum (1935). According to the contention of the Brazilian workers (1938a, b), by this procedure, the presence of any depressing impurities in leukotaxine, capable *per se* of overshadowing the contractile effect on the intestine of histamine, would thus be eliminated. The final extracted material not only fails to produce a positive Zimmermann reaction for histamine, but it fails to induce an enhanced contraction of the isolated segment of guinea pig intestine. Subsequent application of histamine to the same segment is followed by a powerful contraction, indicating thus the absence of any refractory effect. (Barsoum and Gaddum, 1935). These additional observations of leukotaxine render it difficult even to consider the possibility of its identity with histamine.

In view of the accumulated evidences Bier has recently retracted his original claim that histamine and leukotaxine (*i.e.*, the permeability factor) are identical substances (personal communication, 1939). His present argument, however, that leukotaxine may perhaps liberate histamine which in turn can act on the capillary wall, is not substantiated by any observations. On the contrary, recent studies by the writer on the ova of sea urchins (*Arbacia punctulata*) indicate that leukotaxine markedly enhances cellular permeability to water (1940b). Lucké has failed to show any such effects with histamine (personal communication). This would support the view that leukotaxine affects cellular permeability without the intermediary presence of histamine.

Recently Rocha e Silva and Dragstedt have reported observations tending to correlate the histamine equivalent of extracts of various tissues with their capacity to induce increased capillary permeability (1941). These investigators have failed to take cognizance of the fact that in such extracts leukotaxine may likewise be liberated as a result of cellular injury during the mechanical process of grinding and extracting the tissue. Their views have been severely criticized by Menkin (1941a) who has advanced new observations indicating that leukotaxine added to the inactive dialyzed exudate fraction, presumably free of histamine and of leukotaxine, can reconstitute the biological effect of the whole exudate whereas the substitution of histamine fails to accomplish a similar result. These experiments in addition to

previous observations demonstrate that leukotaxine and not histamine is primarily responsible for the mechanism of increased capillary permeability in inflammation.

In connection with the method utilized to identify the presence of a permeability factor in exudates, it is interesting to note that the writer has also been able to demonstrate that cortin, an extract of the adrenal cortex, is *per se* capable of inhibiting either completely or in part, the accumulation of dye in a skin area previously inoculated with either exudate or testicular extract (1940c, 1942a). The addition of cortin to an exudate or to leukotaxine and the subsequent injection of the mixture into a cutaneous layer seems thus to counteract the usual effect elicited by the permeability factor of exudates. These observations may perhaps be of some significance in explaining the rôle of the cortical hormone in traumatic shock (Swingle *et al.*, 1933). Furthermore, the method utilized by the writer may have practical application in the assaying of extracts of the adrenal cortex. These findings regarding the inhibitory effect of extracts of the adrenal cortex on increased capillary permeability have recently been confirmed by Freed and Lindner (1941).

In conclusion, the available evidence therefore indicates the presence in inflammatory exudates of a factor, other than histamine, which induces a prompt increase in the permeability of normal capillaries. A method for its isolation and purification has already been described in detail elsewhere (Menkin, 1938b, 1940a). In its essential features, this consists in treating the exudate with pyridine followed with acetone. After separation of the protein fractions, further purification can be obtained by prolonged extraction with butyl alcohol. The butyl alcohol supernatant fraction is then concentrated to about $\frac{1}{3}$ of its original volume and subjected to low temperature in an ordinary refrigerator. The latter procedure favors spontaneous separation of the active principle. The purified material is a crystalline, doubly refractive, nitrogenous substance which is more or less free of any gross, viscous impurities. A somewhat simplified method for the extraction of leukotaxine, which is a slight modification of the original scheme, is shown in Table 1.

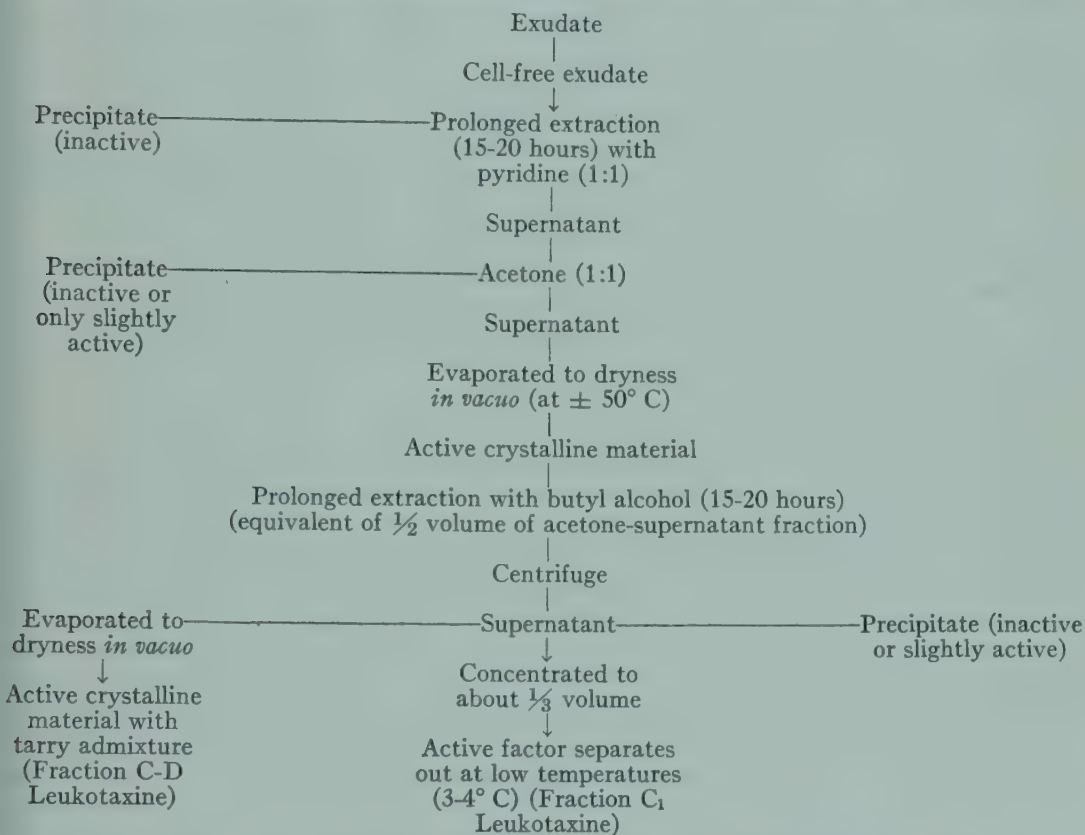

The purified crystalline substance is capable of inducing increased capillary permeability in dilution ranging from 1:100,000 to 1:10,000,000. This indicates considerable purification, for the untreated exudate displays practically no reactivity when diluted above 1 part in 10. The end-product obtained by a variety of methods (Menkin, 1938b, 1940a) is essentially of the same pattern. This is characterized by the formation of discrete aggregates of doubly refractive granules, of needle-like or small rod-like crystals, or a mixture of both types of crystalline material. The crystals usually appear as if they are bound together by the presence of an ill-defined, greyish, homogeneous matrix. From an aqueous medium the crystalline material upon gradual dehydration of the medium occasionally separates out in the form of beautiful needle-like crystals. The similarity of the end-product obtained by different analytical procedures strongly suggests that one is dealing with the same active substance. This crystalline material is extremely active in reproducing the two basic sequences encountered in the development of the inflammatory reaction, namely, increased capillary permeability and prompt leukocytic migration. In view of its additional chemotactic property, which is to be described presently, the writer has named this active substance *leukotaxine*. Minami and Inugami have recently repeated the studies of Menkin on the isolation of leukotaxine from exudates (1940). Their findings fully confirm his original observations, and besides, apparently suggest the liberation of a larger quantity of leukotaxine from an allergic than from a non-specific inflamed area.

Properties of Leukotaxine. The exact chemical identification of leukotaxine requires further studies. These are now in progress. As pointed out above, this substance is certainly not histamine. Physiological tests indicate that it is neither acetylcholine nor an adenylic compound (Menkin and Kadish, 1938). A recent quantitative analysis of a sample of leukotaxine (fraction N; see Menkin, 1940a)

has revealed the following data: C, 50.67%; H, 9.24%; N, 7.65%; Cl, 1.3%; P, 2.06%; S, none; residue, 2.81%. A trace of sodium (6.4%) has been recovered from one of the partially purified fractions studied (C-D fraction, Table 1).

When separated in large measure from inorganic substances by any of the methods described (Menkin, 1938a, b, 1940a, Table 1), the active material usually appears as a slightly brownish, hygroscopic, doubly refractive crystalline material.

Table 1. Scheme of Extraction of Leukotaxine from Inflammatory Exudates (Permeability Factor)

Its solubility in water seems to depend somewhat on the extent of what appear to be adhering impurities, possibly lipoidal in character. The C-D fraction (Table 1), for instance, as reported previously (1940a), is relatively insoluble in water, forming a cloudy suspension in this medium. On the other hand, the C₁ fraction (Table 1) which is presumably further purified is at least moderately soluble in water. Leukotaxine is dissolved by glacial acetic acid or nitric acid but not by hydrochloric acid. The purified fraction (*e.g.*, C₁) is weakly soluble in acetone. An excess of this organic solvent will precipitate out the active material from the pyridine supernatant fraction. It is insoluble in ether. It appears to be soluble to varying degrees in all the lower alcohols tested, being extremely soluble in methyl alcohol.

Hydrolysis for about 20 hours in 5N HCl or 9.5N NaOH inactivates the material. Hydrolysis, however, with normal NaOH fails either to destroy its activity or to dissociate the permeability from the chemotactic factor by inactivation of the former (*cf.* this fact with the statement of Bier and Rocha e Silva, 1938b).

The material is thermostable. When brought to 100° it is found still active. Heating it *in vacuo* at 85°C for eleven hours has failed to reduce its activity. In a similar fashion, when exposed for several days at -20° the material retains full potency. In its present stage of purification the active material fails to show a sharp

melting point. From about 200° leukotaxine begins to char; and at 300° it still has not melted.

The active permeability factor readily diffuses through a cellophane membrane upon dialysis of the untreated exudate (Menkin, 1936a, 1941a). Dr. Sheldon C. Sommers, in the writer's laboratory, utilizing the osmotic method of G. Barger (Pregl, 1937) determined the molecular weight of leukotaxine (fraction C₁). His results indicate values ranging from 2300 to 7400 with most values falling around 6000-7000. When dextrose was used as the comparison substance the values for the molecular weight of leukotaxine were all of a lower order being around 2500. On the other hand, when CaCl₂ was utilized in the method as a more hygroscopic substance and thereby as a comparative substance more akin to leukotaxine, *i.e.*, in this particular respect only, the values were of a distinctly higher order, averaging 6625. On the other hand, the diffusibility of the active material through a cellophane membrane, as revealed by the dialysis of the untreated exudative material, suggests that the molecular weight of leukotaxine is presumably somewhat lower than 5000. It is conceivable that some of the slightly higher values obtained may well be referable to impurities in the material at its present stage of purification. It is to be recalled also that results with the particular method employed in the determination of molecular weight can at best be considered merely as a first approximation. With further purification, studies with other recognized methods will doubtless be undertaken.

The purified active substance yields a negative biuret reaction indicating that it probably is not a protein. The Millon test is likewise negative. The xanthoproteic test is positive indicating thus the presence of a benzene nucleus in an intermediary product of protein catabolism. The Adamkiewicz reaction is likewise positive, pointing to the presence of tryptophane or at least of the indole nucleus. Quantitative determinations of the tryptophane content of leukotaxine by the method of Adamkiewicz and Hopkins (see Block and Bolling, 1940) indicate an average concentration of 1.37 per cent. The ninhydrin test is strongly positive, supporting thus the view that the active substance has at least one alpha-amino group that is free. The reaction with lead acetate or the nitroprusside test fails to reveal the presence of sulphur. These various tests in addition to the diffusibility and thermostability of leukotaxine point to the view that this active permeability factor is not a protein but probably an intermediary product of proteolysis. In this connection it is interesting to note that a proteolytic enzyme, incubated with an otherwise relatively inactive blood serum, favors the formation of products that increase vascular permeability and induce leukocytic migration (Menkin, 1938c). Duthie and Chain (1939) have recently confirmed in large part the studies and views of the writer on the nature of leukotaxine by obtaining a polypeptide from the peptic hydrolysate of blood fibrin that induces an identical biological effect.

Proteolysis is a cardinal feature of the inflammatory reaction (Opie, 1910; Menkin, 1938b, 1940a, 1941b). The level of amino acid nitrogen in exudates is definitely higher than that in blood serum, whereas the total protein concentration in these two fluids is reversed, that in exudate being definitely lower than in blood (Menkin, 1938b). This type of reciprocal relationship confirms the observations of a number of workers concerning the proteolytic activity of exudates, leading thus through this process to the formation of a number of split products. That one of these, or perhaps a group of related compounds may play an important rôle in the mechanism of increased capillary permeability seems a reasonable supposition. The available evidences support this view. The relative homogeneity of the active crystalline material recovered from exudates favors the idea of a single substance to explain the permeability phenomena. The possibility, however, of the existence in exudates of other active substances is not precluded by the data on hand. The present

evidence merely indicates that there exists a factor in whole exudates which alters the normal permeability of capillaries. Analysis of exudates from various species (dog, rabbit, man) reveals the presence of what appears to be a single crystalline substance which *per se* is capable of producing the same effect on the capillary wall as the whole exudate.

The various tests outlined above, in addition to the apparent zwitterionic or dipolar ionic property of the permeability factor, the capacity of saturated ammonium sulfate and of 5 per cent phosphomolybdic acid to precipitate it, and finally its diffusibility through a cellophane membrane, all suggest that the active crystalline substance may well be a relatively simple intermediary product of protein catabolism. It appears unlikely that it is either a proteose, a peptone or an amino acid. The available data are not inconsistent with the fact that this active substance can belong to the group of simple polypeptides. As will be pointed out below, however, this does not preclude the possibility of an additional prosthetic group.

Dr. Sommers has studied, by the method of Van Slyke (1929), in the laboratory of the writer, the amino nitrogen concentration of leukotaxine before and after hydrolysis. The outcome of the measurements may be briefly listed as follows: The amino N concentration of leukotaxine before hydrolysis averages 2.03 mg per 100 mg. This figure represents the results of seven determinations. Leukotaxine samples were then hydrolyzed for about 18 hours in 50 per cent HCl. The amino N content after hydrolysis was found to average 3.54 milligrams per 100 milligrams. These results indicate a ratio of 1.74 when the amino N after hydrolysis is compared with that prior to subjecting the material to such procedure. These facts at first might in themselves suggest that one is possibly dealing with a dipeptide. On the other hand, the nitrogen content of leukotaxine averages 8.65 per cent.* Since the amino nitrogen of leukotaxine was found to average 2.03 per cent, this indicates that possibly a large amount of nitrogen in the molecule is not located in the peptide linkage. This fact, therefore, may necessitate the consideration of a possible prosthetic group, such as, for instance, a nucleic or purine ring (but evidently not an adenylic compound, cf. Menkin and Kadish, 1938). These various possibilities are presented to the reader with utmost caution, for it is to be recalled, for instance, that several hours may be required for the release from the guanidine group of arginine of an amount of nitrogen equivalent to one half the total nitrogen of arginine. Since this fact is not reckoned with in the determinations of the amino nitrogen of leukotaxine by the rapid Van Slyke technique, it is entirely possible that some of the nitrogen of leukotaxine might still be bound up in one of the amino acid components. Furthermore, the magnitude of the molecular weight of leukotaxine, granted that it is acceptable as a first approximation, tends to rule out a dipeptide linkage as the sole structure involved in the leukotaxine molecule. The plausibility of a prosthetic group must, therefore, be seriously envisaged. The negative Molisch test would tend to rule out a carbohydrate linkage. A lipoidal grouping or a purine ring in the molecule, besides other possible prosthetic components, remain distinct possibilities. On the other hand, it is to be emphasized that the enzymatic work of the writer (1938c) and of Duthie and Chain (1939) in addition to the various properties of leukotaxine, as outlined above, seem to support the view that in the molecule of this substance there is a relatively simple peptide chain which *per se* appears to be responsible for at least some of its biological activity.

The mechanism of action whereby leukotaxine is capable of increasing capillary, or for that matter, cellular permeability in general, (Menkin, 1940b) is at present

* The nitrogen content of 7.65% cited previously for a sample of leukotaxine (Fraction N, Menkin, 1940a), was obtained by the method of Dumas, whereas the remaining analyses were performed by the method of Wong (1923) and of Folin and Denis (1916). This may in part account for the slight differences in results.

being investigated. The various recent studies on surface tension and particularly an application of the surface film technique of Langmuir loom as distinct possibilities in this endeavor.

Duran-Reynals (1929) described a spreading factor present in extracts of certain tissues, particularly the testis. This agent facilitates the extension of India ink from the site of its cutaneous inoculation. He referred the phenomenon to an enhancement of tissue permeability by the organ extract employed. Observations indicate that the crystalline material recovered from exudates (leukotaxine) is probably unrelated to this spreading factor. The Duran-Reynals substance is relatively thermostable and non-dialyzable, whereas the permeability factor in exudates is both thermostable and dialyzable.* Preliminary studies have shown that in testicular extracts both factors may be present, and that the spreading factor of Duran-Reynals may be dissociated from a heat stable permeability factor which is apparently similar to, if not identical with, the one recovered from inflammatory exudates (Menkin, 1937). Furthermore, the recent studies of Rigdon (1940) essentially confirm the earlier observations of the writer. This investigator finds a permeability factor in various normal tissues by extracting them with saline. It is dubious whether his contention that such a factor is distinct from leukotaxine is fully warranted. Grinding, mashing and teasing a tissue remove all aspects of normality from it. The liberation by this severe procedure of leukotaxine, or at least of a substance closely related to it, is therefore not precluded. Thus the writer, as stated above, has been able to demonstrate the presence of a factor apparently identical with leukotaxine when subjecting normal testicular tissue to the severe treatment involved in saline extraction (1937). A few years ago in unpublished studies the writer has also succeeded in showing the presence of such permeability factor in the extracts of several other organs; but muscle tissue, in accordance with similar findings by Rigdon (1940), was found to contain a relatively low concentration of the active material.

The observations brought forth above suggest that the increased capillary filtration of inflammatory conditions is primarily referable to: 1, a transient elevation in capillary pressure; 2, an increase in capillary permeability.

Do reactions on the part of nerves play a rôle in inducing these capillary changes? This question as yet remains more or less unanswered. Cohnheim (1889) maintained that the primary *modus operandi* accounting for capillary filtration was a molecular alteration of the endothelial wall presumably effected directly by the irritating substance. The result is a prompt increase in capillary permeability. The vasomotor nerves, according to Cohnheim, play no part in the reaction. The reasons presented for arriving at this conclusion are perhaps open to doubt, particularly as Cohnheim seemed to be of the opinion that permeability changes are detectable only some hours after the application of an irritant. In this connection Menkin (1932) has demonstrated an increase in capillary filtration as early as two minutes after the introduction of certain irritants.

Bruce (1910) studied the inflammation produced in the conjunctiva of rabbits by a drop of mustard oil. He reported that the maximal capillary dilatation could be greatly diminished by local anesthesia with cocaine. Furthermore the dilatation fails to appear when the cut nerves are allowed to degenerate. He therefore concluded that the effects must be due to a local nervous mechanism. He referred the mechanism to an axon reflex located in the sensory fibers. These results have essentially been confirmed by Bardy (1915) and by Breslauer (1919).

Krogh (1920) observed that the application of iodine to the frog's tongue produced a violent contraction of the underlying muscles. The capillaries of the mucous membrane strongly dilated and the dilatation extended for a considerable distance. After the application of cocaine to paralyze the sensory nerves and the

* The recent studies of Chain and Duthie (1940) and of others indicate that the spreading factor and the enzyme hyaluronidase may be identical.

nerve endings, a drop of iodine failed to elicit the usual effect. When iodine was applied to the mucous membrane after section and degeneration of the lingual nerves, the affected capillaries became partially dilated over a localized area. Krogh (1922) concluded that, at least for certain substances, nervous reactions play some part in the initial inflammatory symptoms. The nerves which are responsible for the reaction are most likely sensory fibers that induce dilatation through local axon reflexes.

Ricker and Regendanz (1921), after studying the local action of a number of substances on the pancreas and conjunctiva of the rabbit, reject the views of Cohnheim in regard to the rôle of the vascular nervous system in inflammation. These investigators assume, with, however, only meager evidence, an intricate arrangement of vasomotor nerves consisting of constrictor and dilator fibers supplying both arteries and capillaries. They contend that tissue alterations caused by the presence of an irritant are, in the last analysis, due to local circulatory disturbances arising through stimulation of involved vasomotor nerves.

More recently the studies of Inutsuka (1928) confirmed the earlier observations of Samuel (1890) and the later ones of Meltzer and Meltzer (1903) on the effect of sectioning the cervical or sympathetic nerves in enhancing exudation. This investigator demonstrated that excision of sympathetic ganglia induces marked exudation.

The stimulation of the peripheral ends of sensory nerves induces vasodilatation of skin vessels (antidromic impulses). Lewis and Marvin (1928) and Ungar *et al.* (1936) are of the opinion that such stimulation favors the liberation of histamine in the skin. Wybauw (1936) on the other hand believes that antidromic impulses release acetylcholine. The available data fail to settle this controversial point. At any rate there seems to be no strong proof that either one of these substances, even though perhaps released, is necessarily concerned with inducing the cutaneous vascular dilatation which results from stimulation of sensory nerves.

The foregoing observations indicate that local nervous reflexes probably play a rôle in modifying the initial development of the inflammatory reaction. The experiments of Landis (1931), cited previously, suggested that the transient increase in capillary pressure following the application of an irritant was apparently referable to a local axon reflex. It is conceivable, in view of these facts, that nerves play a rôle in inflammation merely by inducing a temporary increase in capillary pressure thereby favoring outward filtration. On the other hand, there is little doubt that, as pointed out by Cohnheim, an acute inflammation may develop in the absence of all central nervous influences. The persistent and far more significant phenomenon of increased endothelial permeability in inflammatory processes appears to be primarily referable to the liberation of the permeability factor (leukotaxine) by injured tissue. Whether the release of this active crystalline substance is any way related to initial local axon reflexes; or whether, on the contrary, its presence plays some definite part in the development of such reflexes still remains to be determined.

3. The Migration of Leukocytes into Inflamed Tissue. The preceding sections have dealt with capillary changes brought about by the presence of an irritant. The increase in capillary permeability allows the outward passage of plasma proteins. The early formation of fibrin in the inflamed area plays an important rôle in immunity by circumscribing the irritant. This phase has been discussed at length previously (Menkin, 1938a, 1940a). It will be considered again but only briefly in a subsequent section.

The significance of phagocytosis in the disposal of an irritant was stressed primarily by the classical studies of Metchnikoff (1892). This phase of the field has been already discussed at length, and lack of space prevents any detailed reference to it (cf. Mudd, McCutcheon, and Lucké, 1934; Menkin, 1940a). In brief, it has been pointed out that phagocytosis may be influenced by various factors, such as, for instance: temperature, osmotic pressure, the presence of certain ions, or the pH. The most important element that seems to favor phagocytosis consists in the presence

of opsonins or tropins from either normal or immune serum. By forming a protein film around the particles or bacteria, these **phagocytosis-promoting substances** enhance the phagocytic capacity of leukocytes. The globulin fraction of serum seems to contain these active substances capable of favoring phagocytosis by both polymorphonuclear leukocytes and macrophages. The relation of phagocytosis to various surface properties is to be borne in mind, as well as a consideration of the problem from the standpoint of interfacial forces.

The importance of the emigration of leukocytes into injured tissue was demonstrated in the middle of the nineteenth century by Cohnheim (1867). The attraction of leukocytes to a site of injury is an old concept dating back to the work of Leber in 1879. This investigator found a chemotactic substance in the bodies of dead cultures of staphylococci. This substance, which he called *phlogosin*, was found capable of attracting leukocytes in tissues. The early work of Massart and Bordet indicated the chemotactic influence exerted by the products of leukocytic disintegration (1891). Gabritchevsky (1890) studied a number of substances, such as lactic acid, which actually have a repellent action on white cells (the so-called "negative chemotaxis"). Dead or living cultures of bacteria, on the other hand, were found to incite strong positive chemotaxis. Buchner (1890) reported the finding of a protein from the Friedlander organism, capable of exerting a strong chemotactic influence. He found that glycine and leucine were definitely chemotactic whereas tyrosine and trimethylamine failed to attract leukocytes. Wolf studied the phenomenon of chemotaxis *in vitro* (1921). She found that the calcium ion was the only inorganic ion which *per se* was positively chemotactic. She reported that, to a certain extent, all amino acids and amines are likewise positively chemotactic.

Grand and Chambers several years ago reported that mechanically injured tissues liberate thermolabile substances which are positively chemotactic for polymorphonuclear leukocytes (1937). Dixon and McCutcheon studied chemotropism of polymorphonuclear leukocytes *in vitro*. Their results led them to conclude that the chemotropic response is one of direction only. The rate of motion depends on other factors such as the osmotic pressure of the medium, temperature, or the internal condition of the cell (1936). These workers found that, whereas polymorphonuclear leukocytes were strongly attracted by staphylococci or tubercle bacilli, lymphocytes failed to exhibit any chemotropism (1935). Very careful observations on the emigration of leukocytes in the living animal (amphibian larvae and rabbits) were recorded by Clark and his collaborators (1920, 1936). In general these investigators noted that the emigration of leukocytes commences on the average about 2½ hours after the injection of the irritant (croton oil). The majority of the cells were polymorphonuclear leukocytes. Relatively fewer monocytes or lymphocytes migrated through the endothelial wall. Furthermore, the period of emigration lasted only several hours. After a while the endothelial wall seemed to undergo a reversal in consistency which prevented further migration. Strong chemotactic response by polymorphonuclear leukocytes was not necessarily accompanied by active phagocytosis on the part of these cells.

The mechanism of the migration of leukocytes to an area of injury has not yet been satisfactorily explained. Nordmann and Ruether (1930) believe that the phenomenon is dependent on a retardation of blood flow in an inflamed area. The hypothesis that migration of leukocytes is referable to changes in surface tension or that the difference in potential between normal and injured tissue favors the wandering into injured tissue of negatively charged leukocytes is still in large part the result of inference (Abramson, 1927, 1933; Weden, 1933). There is as yet little direct experimental observation to substantiate these views. Grant and Wood (1928) reported that histamine fails to induce leukocytic migration. They, therefore, concluded that the release of histamine from injured tissue does not provide a

complete explanation of the process of inflammation. Moon (1935) essentially confirmed these observations.

As described in the foregoing, the writer isolated a crystalline nitrogenous substance from inflammatory exudates which is *per se* capable of inducing a marked increase in capillary permeability. The substance is concerned not merely with an alteration in the permeability of small vessels but also with the mechanism of leukocytic migration (Menkin, 1937, 1938d). The introduction into the skin of rabbits of this active material induces an almost immediate increase in capillary permeability followed by rapid migration of polymorphonuclear leukocytes. Within 15 to 20 minutes the lumina of the small cutaneous vessels are crowded with these cells, many of which adhere to the endothelial lining. Within 30 to 40 minutes the extracapillary areas are seen to contain a considerable number of polymorphonuclear leukocytes that have migrated outward from the blood stream (Fig. 1).

FIGURE 1. Cutaneous vessels 41 minutes after the intradermal inoculation of leukotaxine. The migration and perivascular infiltration of polymorphonuclear leukocytes are striking. $\times 680$ approximately. (From Valy Menkin, *J. Exp. Med.*, **67**, 145 (1938).)

This cellular reaction does not seem to be referable to the preliminary enhanced capillary permeability. Strong irritants, such as aleuronat or turpentine, although producing a prompt increase in the permeability of capillaries fail to induce a rapid chemotactic effect. Furthermore, this active substance, which, as pointed out above, has been named *leukotaxine*, is *per se* chemotactic as indicated by *in vitro* tests, as well as by observations on the accumulation of white cells in glass capillary tubes containing the active material. For instance, placing particles of leukotaxine on a slide induces a rapid collection and characteristic clustering of leukocytes around such particles (Menkin, 1940a). The available evidence supports the view that the permeability factor and the chemotactic factor are referable to one and the same crystalline substance. Leukotaxine, as pointed out above, seems to belong to the group of relatively simple polypeptides with perhaps a prosthetic component.

It is conceivable that the formation of leukotaxine from injured cells results from an interference with normal protein catabolism induced by the presence of an irri-

tant. The basic sequences of the inflammatory reaction, namely the initial increase in capillary permeability followed by leukocytic migration, are thus perhaps referable to a common denominator: the liberation of leukotaxine. Variation in type and in intensity of cellular infiltration may be in part a function of the local concentration of leukotaxine. There are doubtless other factors involved in the development of the inflammatory reaction. For instance, fibrin formation and thrombosis of small vessels do not seem to be directly related to the presence of leukotaxine (Menkin, 1938a). Unpublished observations indicate that leukotaxine, in addition to altering the permeability of the small vessels and inducing rapid leukocytic migration, produces probably little tissue injury. The latter is apparently due to another factor termed *necrosin* which will be described subsequently. There is, however, some evidence that leukotaxine definitely affects normal cell division. Recent studies by the writer on the ova of sea urchins (*Arbacia punctulata*) indicate that this substance not only increases markedly the permeability of the cell to water but also influences its subsequent development. Fertilization of such leukotaxine-treated ova is followed by a retardation in the rate of cell division and by the appearance of atypical cleavage (Fig. 2). The sperm of sea urchins exposed to leukotaxine are

FIGURE 2. (1) Normal cleavage of a fertilized ovum of *Arbacia punctulata*. (2) Note the unequal cleavage and the retarded development of a fertilized ovum of *Arbacia punctulata* which had previously been immersed in a medium containing leukotaxine. The interval after fertilization is the same in both ova. From Valy Menkin, *Proc. Soc. Exp. Biol. Med.*, **44**, 588 (1940).

likewise inactivated (1940b). These facts, coupled with the effect on the permeability of the endothelial wall, therefore strongly suggest that leukotaxine induces some degree of relatively mild cellular injury.

Furthermore, studies to be discussed in the next section indicate that the leukocytosis which frequently accompanies severe inflammatory conditions is apparently not referable to the liberation of leukotaxine. This substance seems to be concerned with the mechanism of migration without directly affecting the number of leukocytes in the circulating blood. By such studies the writer has succeeded in dissociating the factors concerned with the mechanism of diapedesis from that which regulates the hematogenous picture of infectious processes (Menkin, 1938a, 1939c, 1940a, c).

The observations described above clearly indicate that the presence of an irritant in tissue induces the liberation of various products of protein catabolism. One of

these split products is probably leukotaxine which is *per se* capable of initiating some of the basic sequences of the inflammatory reaction. It is conceivable, however, that the irritant may also possess chemotactic properties which by superimposition might thus enhance the effect of the liberated leukotaxine. This, if true, may be a factor in distinguishing the ultimate character of various types of infectious lesions. For instance, the writer has recently succeeded in obtaining from a virulent culture of staphylococcus aureus, a substance which when injected intracutaneously in rabbits, induces rapid leukocytic migration (unpublished studies). This active material is probably of the same nature as the chemotactic substance originally described by Leber (1879). It is curious to note that living virulent cultures of this microorganism produce in rabbits relatively little cellular infiltration (Delaunay, 1938). One wonders whether the presence of leucocidin elaborated by the living microbe overcomes its chemotactic capacity. Chemical extraction may very well destroy the relatively thermolabile leucocidin without appreciably affecting the potency of its heat stable leukotaxine-like component. These questions are of definite importance and therefore are accordingly being investigated further.

4. Mechanism of Leukocytosis with Inflammation. Does leukotaxine *per se* induce an increase in the level of leukocytes in the blood stream? Although leukocytosis is well known not to be an invariable accompaniment of an inflammatory reaction, some authors, nevertheless, have expressed the opinion that diapedesis and the level of circulating leukocytes may be referable to one and the same factor. Moon (1938), for instance, assumes that "probably the same substances which attract the leukocytes into areas of local injury, produce a systemic mobilization of leukocytes when released in large amounts following extensive injury."

Recent observations indicate (Menkin, 1939c, 1940a, c) that the liberation of leukotaxine evidently bears no relation to the degree of leukocytosis frequently encountered in association with inflammatory processes. Furthermore, the heightened leukocyte level in the blood seems to be referable to the liberation, at the site of injury, of a leukocytosis-promoting factor. The independence of the chemotactic factor from that concerned with leukocytosis is not wholly surprising when it is recalled that certain inflammatory processes characterized by marked leukocytic infiltration can even be accompanied by distinct leukopenia.

a. The Effect of Leukotaxine on the Number of Leukocytes in the Circulating Blood. Experiments were performed on rabbits and dogs. When, after several preliminary counts on peripheral blood samples, the normal leukocytic rhythm had been established, leukotaxine, extracted as previously described from inflammatory exudates of dogs, was injected into rabbits or dogs, either subcutaneously or intravenously. The results of numerous experiments show that repeated injections of this substance even over a prolonged interval of time fail to increase the level of leukocytes in the circulating blood stream. The conspicuous degree of cellular infiltration and abscess formation occasionally encountered at the site of repeated leukotaxine injections in rabbits bears evidently no direct relation to the number of circulating leukocytes.

b. Presence of a Leukocytosis-promoting Factor in Inflammatory Exudates. Having apparently eliminated leukotaxine as the factor responsible for the state of leukocytosis frequently associated with inflammation, studies were undertaken by the writer in an endeavor to determine whether the active principle might not be liberated in the exudate as a result of tissue injury (Menkin, 1939c, 1940a, c).

Danzer (1930) showed that the injection in rabbits of various extracts of organs deflects the polymorphonuclear count. The extracts were prepared from normal muscle, liver, brain, and testis by shaking the minced tissue in isotonic sodium chloride. Nettleship (1938) recently reported experiments on the production of acute inflammation by hemolytic streptococci. The procedure induces leukocytosis in rabbits. This worker correlated the rise in white blood cell counts with the extent

of cytoplasmic damage in leukocytes at the site of inflammation. From this type of histological correlation Nettleship concluded that substances released from injured leukocytes are responsible for the developing leukocytosis. Ponder and MacLeod (1938) recently expressed the opinion that in the blood stream of rabbits with peritonitis the resultant shift to the left of polymorphonuclear counts is probably referable to the absorption of breakdown products of the cells appearing first in the exudate. These investigators demonstrated that the repeated injection of an irritant into the peritoneal cavity is correlated with a showering in the blood stream of very young polymorphonuclear leukocytes of class I or even of metamyelocytes.

FIGURE 3. Repeated injections of pentnucleotide solution into the blood stream of a dog induced only a slight increase in the number of circulating leukocytes, whereas one injection of the LPF, recovered as the active globulin from a sample of exudate, induced a marked rise in the white blood cell counts.

Inflammatory exudates were obtained, as described previously, from dogs subsequent to intrapleural injections of 1.5 cc of turpentine (Menkin, 1934).^{*} The duration of the inflammatory reaction prior to thoracentesis varied from one to several days. From 15 to 25 cc of the freshly removed exudate was injected by intracardiac puncture into the circulating blood stream of a normal dog.

The results of the experiments pointed to a conspicuous rise in the leukocyte counts several hours after the administration of an exudate. The increase in leukocytes averaged about 75 per cent. The normal variation in the leukocyte counts of a number of dogs averaged about 25 per cent. Therefore, the effect of the leukocytosis-promoting factor induced a three-fold increase in the number of circulating leukocytes. The outcome of a few of the experiments, however, suggests that an exudate from an animal with marked leukopenia contains a reduced amount of leukocytosis-promoting factor.

The identification of the leukocytosis-promoting factor in inflammatory exudates of animals with concomitant leukocytosis as well as the failure of leukotaxine to alter the level of circulating white blood cells, indicates that the migration of leukocytes to the point of injury seems scarcely referable to the same mechanism which

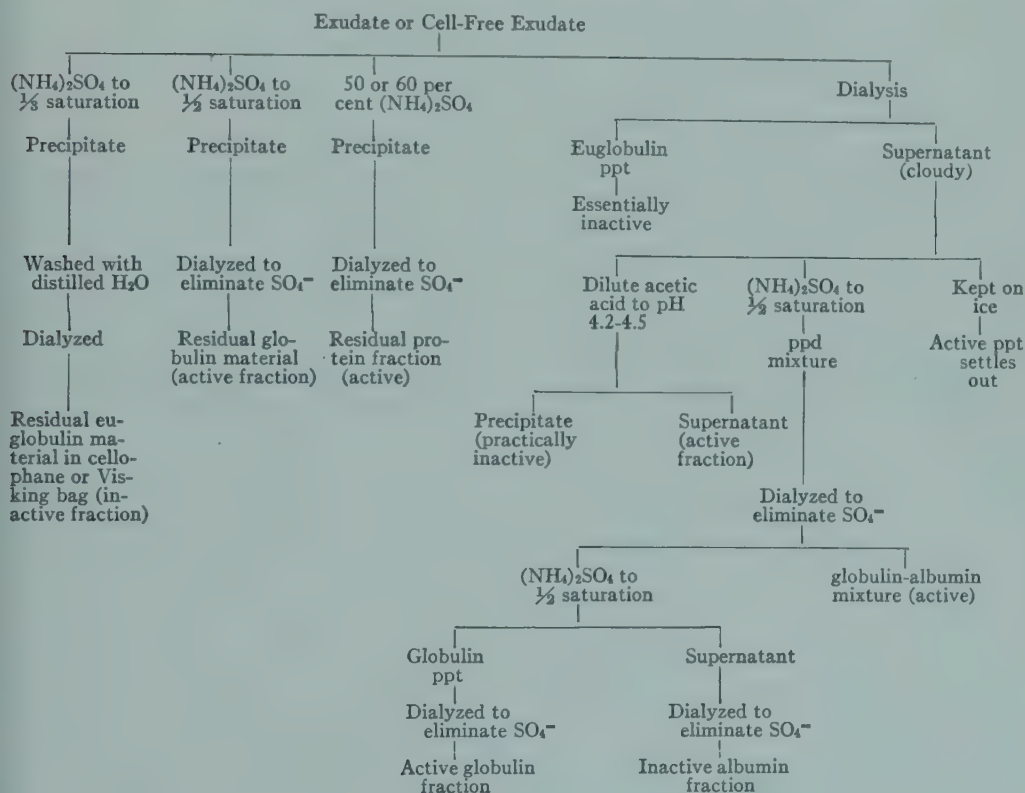

^{*}Other types of exudates were also utilized, e.g. as obtained following a burn, injection of croton oil in olive oil, or from pleural effusions in man.

is responsible for the accompanying leukocytosis. Contrary to the properties of leukotaxine, the leukocytosis-promoting factor is thermolabile and essentially indiffusible through a cellophane membrane. The action of this factor seems to be on the bone marrow, causing a discharge of relatively immature leukocytes into the circulating blood stream (Menkin, 1940c). Studies have indicated that the leukocytosis-promoting factor fails to exert precisely the same type of effect on leukocytes as is elicited by adenosine, histamine, yeast nucleic acid or pentnucleotides. The effect of pentnucleotides on the circulating leukocytes is considerably less intense than that obtained with the leukocytosis-promoting factor (see Fig. 3).

Some of the properties of the leukocytosis-promoting factor have suggested the possibility that it may be a protein or perhaps a product of protein catabolism. Protein fractionation of exudates, presently to be described, supports the view that the leukocytosis-promoting factor is a globulin or is at least in close association with the globulin fraction of exudate.

c. Protein Fractionation of Inflammatory Exudates. In an endeavor to identify the leukocytosis-promoting factor in exudates, the material was analyzed by several different methods. The general scheme utilized is summarized in Tables 2 and 3

Table 2. Scheme of Extraction of Leukocytosis-Promoting Factor

(Menkin, 1940d, e). In brief, the main features indicate that the euglobulin fraction of exudates obtained by dialysis or else by precipitation with ammonium sulfate at one-third saturation is essentially inactive. On the other hand, the fractions obtained after precipitation at one-half saturation or with 50-60 per cent of $(\text{NH}_4)_2\text{SO}_4$ contain the leukocytosis-promoting factor. Precipitation at pH 4.2-4.5 with acetic acid fails to carry down the active principle. Whether this precipitate is a protein nucleate or a nucleo-protein remains to be investigated (Sevag and

Smolens, 1941). The leukocytosis-promoting factor (termed the LPF) is not present in the albumin fraction, as shown in Table 2. These facts therefore seem to localize the LPF in the pseudoglobulin fraction of inflammatory exudates. The material can be obtained in the dried state with relatively little loss in its biological

Table 3. Purification of LPF

potency. The effects of the various fractions derived from the exudative material are graphically represented in Fig. 4. The course of an experiment is also illustrated in Fig. 5.

The action of the LPF is evidently on the bone marrow, causing a discharge of immature granulocytes into the circulation (Menkin, 1940c). Recent studies indicate that this substance presumably penetrates from the site of inflammation into the circulating blood stream for it can be extracted from the serum of such animals. Under ordinary circumstances it cannot be recovered from the serum of normal

FIGURE 4. A diagrammatic representation summarizing the average effects of exudates, of blood serum and of various fractions of exudates on the level of white blood cells. The normal range of fluctuation in the leukocyte counts of several dogs is shown in the first column.

dogs (Menkin and Kadish, 1942, *Archives of Pathology*, **33**, 193). This fact coupled with the observation that neurogenic influences seem to play no part in the development of the leukocytosis accompanying acute inflammation, strongly points to the action of the LPF on the bone marrow via the blood stream (Menkin, 1940a).

The leukocytosis-promoting factor has been recovered originally from exudates of dogs and rabbits (Menkin, 1940a). Reifenstein and his collaborators have recently confirmed its finding in the exudates of rabbits (1941). Studies by the writer and his associates reveal likewise its presence in inflammatory exudates of man (*Archives of Pathology*, **33**, 188 (1942)).

FIGURE 5. The effect of an exudate and of several fractions of exudative material, injected into the circulation, on the leukocyte counts of a dog. The respective fractions utilized and the time of their injection are indicated on the chart.

Longsworth, Shedlovsky and MacInnes (1939) have called attention to the increase in alpha globulin as shown by electrophoretic measurements and to the consequent high value of the resulting proportion of alpha globulin to albumin in the blood serum of patients afflicted with various inflammatory processes. The alpha globulin is presumably in the pseudo-globulin fraction. It is conceivable that the findings of these investigators are due to an excess of globulin containing the leukocytosis-promoting factor that has in turn penetrated from the site of inflammation into the circulating blood. The recent findings, as pointed out above, that the LPF is recovered from the serum of animals with concomitant inflammation would add support to the possibility of such an interpretation (Menkin and Kadish, 1942). It is also possible that the leukocytosis-promoting factor may prove to have clinical application in a number of infectious conditions. Its action on the leukocyte level, as shown previously (Fig. 3), seems to be considerably more effective than that obtained with a commercial preparation of pentnucleotide.*

In conclusion, the mechanism of increased capillary permeability and of leukocytic migration in an inflamed area seems primarily referable to a thermostable, diffusible, nitrogenous substance termed leukotaxine, which is presumably a split product of protein catabolism. On the other hand, the rise in the number of circulating leukocytes seems to be referable to the presence of a thermolabile, non-diffusible protein-like substance in exudates which appears to be either a pseudo-globulin or at least to be linked primarily with this protein fraction. It presumably penetrates into the circulation from the site of inflammation whence it is recovered

* The pentnucleotide preparation was obtained through the courtesy of Smith, Kline, and French laboratories of Philadelphia.

in measurable quantities from the blood serum. The leukocytosis-promoting factor induces a discharge of immature leukocytes from the bone marrow. Studies are now in progress in an effort to purify further this active globulin-like substance which *per se* offers an explanation for the mechanism of leukocytosis accompanying inflammation. The recent finding (1943) that injury in inflammation is referable to the liberation of necrosin, which is located in the euglobulin fraction of exudates, and the further observation that necrosin is responsible for the development of leucopenia, has suggested preliminary removal of necrosin in the further purification of the leukocytosis-promoting factor. This step has yielded extremely potent fractions of this LP factor, capable of increasing the leukocyte level 200 to 300 per cent. (Menkin, *Am. J. Med. Sci.*, 205, 363 (1943).) Finally, recent observations indicate that the leukocytosis-promoting factor induces marked hyperplasia of the bone marrow (Menkin, *New England J. of Med.*, Sept. 23rd, 1943).

5. Cellular Sequences in Inflammation. For many years it has been known that the cytologic sequence in acute inflammation is characterized in the earliest stages by active migration of polymorphonuclear leukocytes. After a time this is followed by infiltration of mononuclear phagocytes or macrophages.

Space does not permit a discussion of the various views concerning the origin of the macrophages in inflammation. Suffice it to say that some investigators, notably Möllendorff, believe that macrophages are derived *in situ* by amitotic division of fibrocytes (1927). Weatherford has obtained further evidence indicating that in the earliest phase of inflammation a conversion of fibrocytes into histiocytes can readily take place (1933). Maximow and Bloom on the contrary deny this contention (1935). Bloom believes that most of the mononuclear cells in inflammation migrate from the blood and are transformed lymphocytes and monocytes. Relatively few of the cells originate from the macrophages already present in the affected tissue. Clark and his collaborators (1936) recently called attention to the possibility of artefacts. Injured or degenerating polymorphonuclear cells often round up and present the appearance of mononuclear cells, round cells, or lymphocytes.

In acute inflammation the polymorphonuclear cells that leave the circulating blood stream form the chief cellular constituents of the early exudate. The mononuclear phagocytes or macrophages increase in number in the later stages. This orderly cytologic sequence in the development of the inflammatory reaction was first pointed out by Borrel (1893) and then by Durham (1897) and Beattie (1903). Such a sequence seems to characterize the majority of acute inflammatory reactions caused by bacteria or by chemical irritants.

No adequate explanation had been offered for this fundamental process. The earlier studies of Müller (1888), of Opie (1905, 1910), and later of Weiss (1927) indicate the presence of proteolytic enzymes in leukocytes. Leukoprotease, found in polymorphonuclear leukocytes, is active only in a neutral or slightly alkaline medium. Lymphoprotease recovered from mononuclear phagocytes is, on the other hand, active in an acid medium. These old observations suggested to the writer that there may be a parallelism between the concentration of hydrogen ions in the exudate and the pH which is optimal for the action of the intracellular enzyme of the predominating type of phagocyte. If this assumption were correct, one might expect in acutely inflamed areas the development of a local acidosis with the shift from polymorphonuclear to mononuclear phagocytes. Lord (1919) in his studies of the pneumonic lung had concluded that in the course of the disease an increase in concentration of hydrogen ion in the exudate probably occurs. Schade and his collaborators (1921) reported that pus from acute abscesses had a pH ranging from 5.95 to 6.50. Menkin studied the relation between the pH of the medium and the cytologic picture during the course of an acute inflammatory reaction (1934). The observations indicated that the predominance of polymorphonuclear leukocytes at

the beginning of an inflammatory reaction is correlated with a pH of the exudate ranging between 7.4 to 7.25 or thereabouts. With the progress of the inflammation the pH may fall to a level of 6.9 or 6.8. At this stage the exudate is characterized by a preponderance of macrophages. The polymorphonuclear cells are found swollen, vacuolated, and appear degenerated. Below a pH of 6.8 or 6.7 all types of leukocytes are injured, and frank pus ensues. Observations indicate that there seems to exist a definite relation between the pH and the cytologic picture of an exudate. When the inflammatory reaction is mild the pH persists above 7.0, and the polymorphonuclear cell type predominates. Furthermore, Evans reported that leukocytes are sensitive to the action of acids (1931). The writer has been able to verify this observation. He has thus shown that polymorphonuclear leukocytes are incapable of survival *in vitro* when exposed to a pH of 6.6 or thereabouts, whereas the macrophages are apparently undamaged (1939d). In brief, with a fairly reasonable degree of certainty, the cytologic picture of an exudate can be predicted from its hydrogen ion concentration and vice versa.* The data suggest that the cytologic picture in inflammation is conditioned by the pH of the exudate. Subsequent studies revealed that the mechanism of local acidosis is often referable to a disturbance in the local intermediary carbohydrate metabolism and in the depletion of the alkali reserve (Menkin and Warner, 1937). When the lymphatic circulation and ultimately the vascular channels are obstructed, as is apt to occur in acutely inflamed tissue, the injured area becomes shunted off from the rest of the organism. It develops its own pH, its own fluid exchange, and its own metabolism. With such impairment in the local circulation, a state of relative anoxemia tends to develop. Perhaps an anaerobic glycolytic type of respiration may result. The plausibility of this view is supported by finding an enhanced glycolysis and a depletion in the alkali reserve. The lactic acid level of the exudate rises with a corresponding drop in sugar level (Fig. 6). The observations thus indicate that the cytologic picture seems to be conditioned by the pH which, in turn, is frequently referable to disturbance in the local carbohydrate metabolism. The possible implications of these findings in regard to a clearer understanding of the histologic manifestations of various lesions are obvious. It is conceivable that the relative absence of leukocytic migration in the late stages of inflammation may be referable to a local increased concentration of lactic acid. This acid is, as has been pointed out above, negatively chemotactic. Its formation in appreciable amounts may thus counteract the migration of white cells induced by the liberation of leukotaxine (Menkin, 1938a, d, 1940a).

6. Chemical Basis of Injury in Inflammation. Neither leukotaxine nor the leukocytosis-promoting factor induces any appreciable degree of tissue injury. Yet inflammation is a manifestation of severe tissue injury. Recent studies (Menkin, 1943) have indicated that the basic pattern of injury in inflammation is referable to the liberation of a factor located in or associated with the euglobulin fraction of exudates. For the sake of convenience this substance has been termed *necrosin*.

The fundamental pattern of inflammation may be influenced by the nature of the irritant or the anatomical site of the lesion. Nevertheless, the basic pattern seems referable to a common denominator, in turn released by the injured cell. This is *necrosin*. In brief, the stereopattern reaction of inflammation is referable to an altered cellular chemistry, which as a result liberates various by-products, such, for instance, as leukotaxine, the leukocytosis-promoting factor, *necrosin*, and even

* Steinberg and Dietz have recently questioned the repeated findings of a great number of investigators concerning the development of local acidosis in acutely inflamed areas (1938). As indicated in detail elsewhere (1938a) by the writer, their contention may primarily be invalidated by a questionable technique in the measurement of pH and by their failure to correlate the leukocytic picture and pH on an identical sample of exudate. Menkin's conclusions have recently received further confirmation in the hands of Lurie (1937) and in the work of Rugiero and Tanturi (1942).

FIGURE 6. Correlation between the hydrogen ion concentration, the conversion of sugar to lactic acid, and the cytological picture of a pleural exudate (Dog 9-2). Note that with the fall in the level of the exudate sugar there is a rise in the concentration of lactic acid and the pH falls notably. This local acidosis is accompanied by a shift in cellular elements. The polymorphonuclear leukocytes are replaced by mononuclear phagocytes.

glucose. It is these common denominators which are in turn responsible for the stereopatterned response. Necrosin displays a considerable number of interesting properties. It is absent in normal blood serum, but it is frequently encountered in the circulation of an animal with a concomitant inflammation. This observation suggests that necrosin is absorbed from the site of inflammation into the blood stream. The importance of this fact in regard to the concept of the effect of an inflammation focus to organs at a distance, is obvious. The intramuscular injection of necrosin in dogs invariably injures the liver and very frequently the kidneys. The induced lesions suggest hepatic focal necrosis and small abscesses in the kidneys with injury to the tubules. The possible significance of necrosin absorption in a total explanation of the syndrome of shock, also deserves further study. Furthermore, necrosin induces a severe leukopenia in dogs. It is the only fraction of exudates which causes a sharp fall in the level of circulating leukocytes. This fact has been utilized in a further purification of the leukocytosis-promoting factor (1943b). The significance of this observation (*i.e.*, that necrosin injection is followed by leukopenia) in an endeavor to explain various leucopenic manifestations in certain infectious processes, *e.g.*, typhoid fever, is to be considered. Finally, necrosin is the sole fraction recovered from exudative material which is capable, *per se*, of eliciting fever in dogs. This finding offers definite possibilities in attempting to understand further the mechanism of fever production with inflammation.

INFLAMMATION IN RELATION TO IMMUNITY

In the foregoing discussion an attempt has been made to trace the salient sequences involved in the development of an acute inflammatory reaction. The interdependence of the various manifestations concerned in the disturbance of local fluid exchange, increased capillary permeability, and leukocytic migration produce a complex mechanism which tends to localize and ultimately dispose of the irritant. Some of the implications of this concept of inflammation will now be briefly considered.

The inflammatory reaction plays a definite rôle in localizing the irritating factor, or at least limiting its dissemination, whether it be a bacterial or a chemical irritant. This capacity, which may appropriately be termed *fixation*, contributes a further significance to inflammation in relation to immunity. By delaying the dissemination of obnoxious substances into the circulating blood stream, the inflammatory reaction protects the organism as a whole at the expense of local injury. This view of inflammation has gained considerable ground in the last ten years. Analyses have demonstrated that fixation at the site of inflammation is primarily due to mechanical obstruction caused by a network of fibrin and to occlusion of lymphatic vessels (Menkin, 1931b, c, 1938a, 1940a). Studies on the time relationship have shown that with powerful irritants fixation is the initial phase in the development of a severe inflammatory reaction, and that it precedes even the migration of leukocytes. In view of the available evidence one can ascribe a definite function to the early formation of lymphatic blockade at the site of inflammation. *Fixation* plays a definite rôle in the relation of inflammation to immunity. It may be considered in the same light as the migration of leukocytes and the stage of fibrous repair that follow.

The earlier literature on the rôle of inflammation in immunity dating from the studies of Issayeff (1894) has been considered in detail elsewhere and will therefore be omitted from the present discussion (Menkin, 1938a, 1940a). Considerable evidence, to which the reader is referred in the foregoing publications, have indicated that various substances including bacteria, when introduced into the circulation, rapidly accumulate at the site of inflammation where the material is fixed owing primarily to the establishment of an effective lymphatic blockade (Menkin, 1931b). The conclusions of the writer on the mechanism of fixation, based on numerous experimental observations, contrary to the statement of Bloom (1940), have received support in the hands of Lurie (1939), Burrows (1932), Clark and Clark (1937), Dennis and Berberian (1934) and of Glenn, Peterson, and Drinker (1942). Minor injury favors the dissemination of injected foreign material into the tributary lymphatic channels (Hudack and McMaster, 1931, 1932, 1934). On the other hand, the "walling off" of an acutely inflamed area seems to be due to an enhanced passage of fibrinogen through the more permeable capillary wall. This fact incidentally points to the importance of a clear understanding of the mechanism of increased capillary permeability in inflammation. The mechanism of fixation, as indicated by three distinct types of evidence, is primarily referable to the formation of a fibrinous network and of thrombi occluding the lumina of draining lymphatics.

The evidence for arriving at this conclusion has been described in detail elsewhere (Menkin, 1931b, 1932, 1935, 1938a, 1940a) and therefore will merely be restated here in brief:

1. Morphological examination substantiates the view that fixation may well be referable to lymphatic blockade caused by fibrin and obstructing thrombi in lymphatic channels (Figs. 7 and 8).

2. It was reasoned that, if mechanical obstruction plays an important rôle in fixation, then substances which are unable to disseminate from an acutely inflamed area should, for the same reason, fail to enter it when injected at the periphery of

the area. This is precisely what was found to occur when trypan blue or bacteria were injected at the periphery of an inflamed focus. Burrows has recently confirmed this experiment with India ink (1932). Studying the living frog under the microscope, the writer has followed the diffusion of a dye from its peripheral inoculation to the boundary of the inflamed area where its further progress was blocked by the presence of a thrombus occluding a lymphatic channel (1931d).

FIGURE 7. Fibrinous network in an area of dense leukocytic infiltration.

3. A third type of evidence which reinforces the hypothesis was obtained by taking advantage of the fact that concentrated urea dissolves fibrin. When this solvent was injected immediately after the irritant, obstructing thrombi failed to form in the tributary lymphatics, and fixation was inhibited. Urea had apparently no other manifest effect on the cytological character of the exudate as revealed by microscopic examination. These three distinct types of evidence render it quite likely, as stated above, that the basic mechanism of fixation in inflammation is primarily referable to an obstructing barrier in the form of thrombi in lymphatics and of coagulated plasma in edematous tissue. There is as yet no precise information on the question of the relation of increased capillary passage to the lymph flow from an inflamed area. Pending such data, the finding of increased lymph flow from a main lymphatic trunk draining a large area of tissue injured unequally by the inflammatory irritant only indicates, as would be expected, an absolute increase in lymph flow. In such an experiment one cannot preclude the possibility of a rela-

tive decrease in the lymph output when the total amount of plasma which has permeated through the capillaries is taken into consideration (Menkin, 1933a). Inflammatory edema may in part be an index of the inability of a partially impaired lymphatic circulation to take care of the excessive passage of fluid from the circulating blood into acutely inflamed tissue. In this connection the interesting observations of Drinker and Field are suggestive and instructive (1933). These investigators have succeeded in developing a conspicuous local edema or elephantiasis in the leg of dogs following obstruction of the lymphatic trunks.

FIGURE 8. Obstructing thrombi in lymphatic channels.

Various secondary factors, such as, for instance, the presence of immune bodies in anaphylactic or allergic inflammation, may reinforce the basic mechanism (Menkin, 1940a). The early occurrence of fixation in a severely injured area plays a definite rôle in immunity, for it allows an interval in which the relatively sluggish leukocytes can assemble for phagocytosis.

a. Inflammation and Bacterial Invasiveness. The foregoing observations on the mechanism of fixation have offered a means of studying a factor that may account in large part for the differences in the invasive ability of various pyogenic organisms.

The intensity and rapidity with which an inflammatory irritant is circumscribed in a tissue area varies with the type of irritant. The speed with which an irritant causes a region to be walled off by thrombosed lymphatics, or a fibrinous network, or by both, is necessarily an important index in determining its ability to disseminate ultimately into the circulating blood. This holds true if the irritant can readily drain through lymphatic vessels from the site of inoculation. That bacteria disseminate from the site of inoculation through lymphatics has frequently been demonstrated (Noetzel, 1906; Wells and Johnstone, 1907). It follows from this that, if bacteria are employed as inflammatory irritants, some information may be obtained concerning the invasive capacities of different microorganisms. This would depend on the type of inflammatory reaction which a given microorganism induces

in the host. In other words, can the behavior of various pyogenic organisms in tissues be related, at least in part, to their respective abilities of inducing an early inflammatory reaction at the site of their inoculation which, by lymphatic blockade, would tend to prevent their dissemination to the tributary lymphatic nodes?

In observations described fully elsewhere (Menkin, 1933b, 1935) it was definitely shown that the respective differences in the invasive behavior of *Staphylococcus aureus*, pneumococci, and hemolytic streptococci was in large part referable to differences in the rapidity and intensity of injury induced by these respective microorganisms. A culture of *Staphylococcus aureus* or of its soluble toxin* induces prompt lymphatic blockage, as indicated by histological examination of the site of inoculation, and also by the fact that within one hour after infection an injected indicator dye fails to reach the regional lymphatic nodes. In the case of hemolytic streptococci, however, about two days are required after their cutaneous inoculation before the local reaction is of sufficient intensity to induce lymphatic obstruction. These observations suggest a paradoxical interpretation. Staphylococci produce in general little systemic effect owing to their intense local injurious reaction which fixes them *in situ*. Streptococci produce marked generalized effects on the organism as a whole because of their comparatively mild local reaction. This allows them relatively free penetration to the essential organs.

The sum total of all the observations, described in detail elsewhere (Menkin, 1936b, 1938a, 1940a), clearly indicates the rôle of the inflammatory reaction in regulating the rapidity of invasiveness of a microorganism, and therefore the significance of this factor in grading the immunity or resistance of the host is manifest. However, the rate of dissemination in no way alters the virulence *per se* of the bacteria, which still remains a most important factor in evaluating resistance. Virulence and invasiveness are therefore regarded as two separate variables in studying problems of immunity (Menkin, 1935, 1936b).

The rapidity and the intensity of local fixation in an inflamed area are factors to be reckoned with in determining the invasiveness of an infectious microorganism. Dissemination seems thus to be related directly to time and inversely to the degree of local injury. This may perhaps be conveniently expressed as follows:

$$D = \frac{Kt}{I}$$

where D refers to dissemination, t to time, I to extent of injury, and K is a constant depending on the physical properties of the irritant and perhaps on the anatomical position of the lesion. Powerfully necrotizing irritants produce, as a result of an increase in capillary permeability and lymphatic damage, an extremely prompt "walling-off" reaction (termed *fixation*). By this early process, the area of injury is mechanically circumscribed and the dissemination of the irritant is prevented. This initial response, which may occur within thirty minutes following the injection of an irritant, allows a definite interval of time for the leukocytes to assemble at the site of inflammation for phagocytosis. *Staphylococcus aureus* is an example of such a bacterial irritant. Aleuronat is a chemical irritant of similar potency (Menkin, 1929). Mild irritants, on the other hand, produce only a delayed reaction thus allowing relatively free penetration of the irritant into the circulation for a considerable interval of time. Occlusion of the draining lymphatics in such instances often takes place as late as two days following the introduction of the irritant. Hemolytic streptococci exemplify this type of irritant (Menkin, 1933b). Another

* The effectiveness of the toxin of *Staphylococcus aureus* in inducing lymphatic blockade is destroyed by heating it to about 58° C for one hour. The action of the toxin seems to be caused by the presence of a factor similar, if not identical, to leukocidin (Menkin, 1935).

instance has been recently demonstrated by McMaster and Hudack who showed that, up to 48 hours following a mere skin incision or local burn, lymph drainage is adequate (1934). Subsequently lymphatics failed to convey effectively materials contained in them. The intensity of fixation is found frequently to parallel the extent of inflammatory edema. This, as already mentioned, would suggest that in an inflamed area the local swelling is at least in part the result of blockage to normal lymphatic drainage which is thus unable to cope adequately with the excess outpouring of plasma from the capillaries.

b. Diabetes and Inflammation. The condition of diabetes mellitus is known to become markedly intensified when complicated by inflammation or infection. No satisfactory explanation has ever been offered to account for the basic mechanism involved. The inflammatory reaction tends to be concomitantly increased in severity and there seems to exist a lowered resistance to infections. There are some observations indicating a diminished capacity for antibody production and a reduction in the bactericidal power of the blood (Richardson, 1933, 1940). Recent observations of the writer have attempted to explain both the enhanced degree of diabetes and the associated increased severity of the inflammatory reaction in diabetic dogs having a superimposed acute pleural inflammation (Menkin, 1941b; 1941c).

All observations were made on dogs rendered diabetic by pancreatectomy. It is to be recalled in this connection that although this type of diabetes has many obvious points of similarities with the human form, nevertheless there are several points of differences (Long, 1936-1937). Three groups of animals were studied as follows: (1) dogs having a pleural inflammation induced by the introduction of 1.5 cc of turpentine; (2) depancreatized dogs with a pleural inflammation induced by the same irritant, but receiving no insulin immediately preceding and during the period of inflammation; (3) depancreatized dogs with pleural inflammation but receiving repeated injections of low doses of insulin (8 to 10 units twice daily) throughout the period of study.

The presence of an acute inflammation in the right pleural cavity of dogs fails to alter the blood sugar level. On the other hand, a similar injurious reaction in a diabetic dog induces a sharp and rapid ascendancy in the blood sugar from an average in the 8 dogs studied of 253 milligrams to a level of 469.1 milligrams per 100 cc. The experimental findings wholly substantiate the well-known clinical picture of a diabetic disorder complicated with infection.

What is the basic mechanism involved to explain the enhanced diabetes? There are two considerations which must first of all be borne in mind. In the first place, as already pointed out, an inflamed area is a focus of proteolysis. This has been pointed out previously by a number of investigators including the writer (1940a). The conspicuous protein catabolic process may be regarded as a cardinal feature of the inflammatory reaction. In the second place, the earlier studies, particularly of Lusk and of his school, have demonstrated that amino products of protein degradation are in the diabetic organism readily converted into sugar (Stiles and Lusk, 1903; Lusk, 1923). Gluconeogenesis from proteins is thus a well-recognized process. It is therefore quite possible that an inflamed area in the diabetic behaves as a focus of enhanced proteolysis, favoring thus the formation of glucose from protein breakdown; the glucose, in turn would gradually diffuse into the circulation. The accentuated degree of proteolysis would offer at the same time a reasonable explanation for the increased severity of an inflammatory reaction in diabetes. Studies have therefore been carried out on both exudate and blood samples of diabetic and non-diabetic dogs to determine the degree of proteolysis at the site of an acute inflammation. Besides measuring the sugar and lactic acid, determinations have also been performed on the total proteins, non-protein nitrogen, urea and amino acid nitrogen concentrations of both exudate and blood.

The results of the determinations on exudates substantiate the view that the inflamed area is an active focus of gluconeogenesis originating from increased protein breakdown. The lactic acid and sugar levels of diabetic exudates are considerably higher than encountered in non-diabetic exudates. The average increase in lactic acid is 52 per cent, while the increase in exudate sugar averages 473.6 per cent. There is a slight drop in total proteins averaging 12.56 per cent. The rise in the products of proteolysis in diabetic exudates is striking. The non-protein nitrogen is increased 89.45 per cent; the urea, 126.3 per cent; and the amino acid nitrogen, 74.29 per cent. These facts therefore indicate an enhanced degree of proteolysis at the site of inflammation in a diabetic animal. That these products of protein breakdown are converted to glucose by deamination is further substantiated by insulin administration. Repeated injections of this substance to depancreatized dogs with inflammation are followed not only by a drop in lactic acid and sugar concentration but also by complete inhibition of the enhanced local proteolytic processes. The total proteins, NPN, urea and amino acid nitrogen are now restored to the levels found in exudates of non-diabetic animals.

The enhanced glucose formation from proteins in the acutely inflamed area allows for the gradual penetration of this diffusible substance into the circulation. Not only is the level of blood sugar, as pointed out above, markedly raised; but there is also a pronounced rise in the concentration of non-protein nitrogen, urea and to some extent of amino acid nitrogen in the systemic circulation. This state of affairs is not referable to pancreatectomy *per se*. Furthermore, the concentration of the exudate sugar is higher than that found in the blood stream, indicating thus that the induced hyperglycemia with inflammation doubtless originates by gluconeogenesis in the inflamed area. The reflection in the blood stream of the rise in a diabetic exudate of intermediary products of carbohydrate and protein metabolism does not contradict the earlier observations of the writer on the fixation or localization of material at the site of inflammation; for, as he has pointed out, particles of smaller dimensions, and of greater diffusibility are less effectively retained in such foci. Such materials therefore gradually find their way into the circulating blood (Menkin, 1938a, 1940a). Inflammation *per se* in non-diabetic dogs fails to induce in the blood any increase in either protein or carbohydrate products of metabolism. Insulin administration by inhibiting gluconeogenesis from proteins at the site of inflammation likewise induces no detectable changes in the levels of the blood.

Finally, the enhanced local proteolysis in the inflamed area of a diabetic animal manifests morphological signs of cellular injury in the form of vacuolized, degenerated leukocytes which are in many instances unidentifiable. The cells studied were from areas of inflammation of several hours' to one day's duration. Comparable studies of non-diabetic exudates revealed normal appearing leukocytes. In agreement with earlier studies by the writer the character and type of the cells in exudates were found to be correlated with the pH and the lactic acid concentration (Menkin, 1934; Menkin and Warner, 1937). Both the hydrogen ion and the lactic acid concentrations were found to be elevated in exudates of diabetic animals.

In conclusion, the mechanism of enhanced diabetes with inflammation seems to be referable to an increased proteolysis in the inflamed area. The rise in protein breakdown processes is correlated both with gluconeogenesis, and with increased severity of the inflammatory reaction. The surplus glucose formed locally gradually diffuses into the circulation thus elevating markedly the blood sugar level (Menkin, 1941c, 1942b).

In a further study (Menkin, 1943b), the writer has shown that at the very beginning of an inflammation in a diabetic dog the level of exudate sugar is considerably more elevated than it is found in the blood stream. This concentration gradient indicates further that gluconeogenesis occurs at the site of inflammation, whence the

glucose gradually diffuses into the circulation. Furthermore, studies on non-diabetic dogs definitely indicate that glucose is formed at the site of injury, but that probably owing to the presence of insulin in non-diabetic dogs, the effect is merely transitory. In diabetic dogs gluconeogenesis at the site of inflammation is sustained and quantitatively exaggerated. But nevertheless from the observations on non-diabetic animals, the principle is evident that injured cells in general are potentially gluconeogenic.

CONCLUSIONS

The term inflammation refers to the aggregation of several interdependent reactions incited by the presence in normal vertebrate tissue of a foreign body or so-called irritant. The injurious agent may be living or non-living; it may be of exogenous or even of endogenous origin. Inflammation as such, is a basic phenomenon in infectious processes. An analysis of the mechanisms involved and their implications to the organism as a whole, especially in the light of modern biological concepts, is obviously of considerable significance. Inflammation is essentially one, among others, of the various manifestations of cellular injury. It represents the complex response on the part of normal tissue to relatively severe damage. There are doubtless other forms of reaction to cell injury. Neoplasia, for instance, may yet prove to be the resultant of such a form. Cellular regeneration is perhaps merely another form of elemental reparative response to injurious stimuli. As we probe further into the intricate mechanisms of cellular physiology and pathology, it is conceivable that the term inflammation may become obsolete and may therefore eventually be discarded. The apparently distinct types of cellular injury may come to be regarded as quantitative variations of a single or perhaps of several basic physiological disturbances. What is now regarded as an inflammatory reaction may in the future be considered only as a prototype of severe cellular injury in tissues of higher animals. Reparative reactions may ultimately be analyzed and considered from a similar angle.

The inflammatory reaction is initiated by a derangement in local fluid exchange. It subsequently proceeds through a series of interdependent sequences which ultimately tend to localize and dispose of the irritant. The disturbances in the local physiology of inflamed tissue are closely associated with the immunological significance of the inflammatory reaction. The principal sequences in the development of inflammation, besides the pattern of severe cellular injury referable to *necrosis* liberation as discussed above, may be listed again as follows:

a. **Increased Fluid Passage Through the Capillary Endothelial Wall.** This seems to be primarily referable to two factors: 1. *Elevation in capillary pressure* which is perhaps the outcome of a local axon reflex affecting the caliber of arterioles. 2. *Increased capillary permeability*; this seems to be referable to the liberation by injured tissue of the permeability factor termed *leukotaxine*. Leukotaxine is a nitrogenous substance, the significant properties of which evidently do not resemble those of histamine. It appears as if it may belong to the group of relatively simply polypeptides, although the presence of a prosthetic group in the molecule remains a distinct possibility. It is postulated that its formation occurs as a result of the presence of an irritant interfering with local protein catabolism.

b. **Localization of the Irritant (fixation).** The "walling-off" of an inflamed area seems to be due to an enhanced passage of fibrinogen through the more permeable capillary wall. The mechanism of fixation is primarily referable to the formation of a fibrinous network and of thrombi occluding the lumina of draining lymphatics. This favors the development of lymphatic blockade in acute inflammation. Various secondary factors, such as the presence of immune bodies in anaphylactic or allergic inflammation, may reinforce the basic mechanism. The early occur-

rence of fixation in a severely injured area plays a definite rôle in immunity for it allows an interval in which the relatively sluggish leukocytes assemble for the purpose of phagocytosis.

c. **Migration of Leukocytes.** The first cells to migrate into an inflamed area are the polymorphonuclear leukocytes. The mechanism of their migration seems to be related to the liberation of *leukotaxine* by injured tissue. The properties of this crystalline nitrogenous substance recovered from exudates offer a reasonable explanation for two of the basic sequences of the inflammatory reaction: first, the initial increase in capillary permeability, and secondly, the rapid emigration of polymorphonuclear leukocytes into injured tissue. Leukotaxine appears to contain factors concerned both with permeability and chemotaxis.

The polymorphonuclear cells are gradually displaced by macrophages. Cytological changes in acute inflammation seem to be conditioned by the pH of the exudate which in turn is often referable to disturbance in the local intermediary carbohydrate metabolism. The development of a local acidosis, resulting from increased glycolysis and depletion of the alkali reserve, seems to injure the polymorphonuclear cells. Macrophages survive and predominate when the pH falls to a level of about 6.9 to 6.8. Further reduction in the pH proves lethal to all types of leukocytes and frank suppuration ensues.

The rise in the level of circulating leukocytes, frequently encountered in infectious processes, seems to be referable to the liberation in the inflamed area of a leukocytosis-promoting factor. This factor is either a globulin or at least it is associated with the pseudo-globulin fraction of exudates. The leucocytosis-promoting factor is also capable of inducing marked hyperplastic growth of granulocytic elements and megakaryocytes in the bone marrow of injected dogs (Menkin, 1943c).

The interplay and dynamic relationships of the above sequences constitute an acute inflammation. An inflamed area can be considered as shunted off from the rest of the organism. It has its own metabolism, its own hydrogen ion concentration, and its own modified circulation. The inflammatory reaction thus displays an extraordinarily complex mechanism tending to localize and dispose of a chemical or bacterial irritant. This ultimately leads to organization and repair of the affected tissue. Recent studies by the writer (1944d) on the relation of cellular injury to proliferative and neoplastic response suggest the possible presence of one or several growth-promoting substances liberated in an inflammatory exudate. Exposure for several months of normal cells to the effect of repeated injections of exudative material induces ultimately in the ears of rabbits a sustained proliferative response on the part of the cartilage and epithelium. There is likewise evidence of metaplastic bone transformation, metaplasia of the epithelium, formation of chondroma-like structures and in a few instances, characteristic papillomatous projections. It is conceivable, in view of such observations which are being studied further, that neoplasia may yet prove to be, as stated above, a manifestation of long standing, but relatively mild, cellular injury brought about either by a protracted inflammatory process or by an alteration in the normal physico-chemical equilibria of the cell. The results of such profound changes in the physiology of the cell may in turn induce the liberation of growth-promoting factors. It is quite possible that ordinary reparative processes at the end stage of the inflammatory reaction are referable merely to the presence of a minimal concentration of such growth-promoting substances.

The increase in local proteolysis at the site of inflammation in diabetes favors both local gluconeogenesis and tissue injury. The surplus glucose diffuses into the circulation and thus offers an explanation for the enhanced hyperglycemia accompanying inflammation. Furthermore, injured cells in general are potentially gluconeogenic.

The concept of fixation and its mechanism afford a rational interpretation of the

rôle of inflammation in immunity. The capacity of pathogenic microorganisms to disseminate from their site of inoculation is apparently inversely related to the intensity of induced local injury. In this way inflammation plays a significant rôle in problems of immunity as a regulator of bacterial invasiveness. It may be truly regarded as the physical basis of infectious processes.

The Modern Outlook on Blood Coagulation

JOHN H. FERGUSON

Departments of Physiology and Pharmacology, University of North Carolina
(formerly Department of Pharmacology, University of Michigan)

The highlights of the major viewpoints that have guided investigators in this difficult field are touched upon in a recent presentation of a new blood-clotting theory.⁴⁹ The subject has many ramifications^{39, 118} involving fundamental principles of physical^{2, 122} and colloid⁹⁸ chemistry, in addition to its interest for the protein,¹⁸ lipid,^{8, 64, 119} carbohydrate (polysaccharide),⁸⁸ and enzyme⁹⁶ chemist and its importance for clinical medicine.^{41, 100} Briefly, the essential feature of blood coagulation is the conversion of *fibrinogen*, a plasma protein fraction, from the state of a colloidal hydrosol to that of an oriented micellar gel, *fibrin*. This process requires a specific agent termed *thrombin* which has first to be elaborated from plasma protein sources in which it exists as an inactive precursor, *prothrombin*.¹⁰² The puzzling problem is to account for the fact that blood does not yield thrombin and clot in the course of the normal circulation, despite our ability to demonstrate, by isolation *in vitro*, even from the plasma devoid of all formed elements (cf.^{26, 32}), all the known factors which lead to the coagulation of shed blood. It is true that we are still only at the threshold of dignifying these isolated factors with true chemical significance, and the important physicochemical aspects are particularly in need of further investigation. Even when the "coagulationist" is forced still to work with relatively crude materials, he can learn much by carefully controlling his tests so as to identify and evaluate the significance of suspected "impurities".²⁸ Recent techniques have been standardized^{36, 100} to give data of definite quantitative significance. Selected references (see bibliography) are given for assay of (1) fibrinogen,^{68, 91} (2) prothrombin,^{7, 42, 99} (3) ionized calcium,^{10, 82, 84, 101} (4) tryptase,^{45, 47, 48} and (5) heparin.^{1, 75} This "progress report" will endeavor to bring out the main points that can be deduced from the modern experimental approach to the blood-coagulation question, considered from the point of view of fundamentals and without reference to the important problems of practical applications, which would unduly extend the scope of this review. Thus, no mention will be made of purely *in vivo* factors such as the *naphthaquinones* (vitamins K²¹) and the prothrombin-lowering dicoumarins.¹²¹

Fibrinogen is isolated in varying degrees of purity by selective precipitation (repeated for "purification") by (a) dilution and acidification (to the isoelectric point),¹⁰² cf.,¹⁸ (b) "salting-out" with neutral salts,⁶⁹ or (c) cold alcohol precipitation.¹⁹ Its preparations are likely to show some degree of (1) "spontaneous" coagulation,¹⁰² (2) denaturation,^{18, 60, 118} and (3) lytic destruction, with loss of ability to yield fibrin.⁴⁴ These are minimal in the best preparations,¹⁹ some of which keep indefinitely in the dry state⁵² and very satisfactorily in sterile saline solution. Solutions that do not yield fibrin "spontaneously" are free from thrombin,¹⁰² and the ability to withstand the addition of the necessary "activators" (see below) of

thrombin-precursor (prothrombin) show this to be absent also.^{36, 41} Failure in experimental application of these principles, incidentally, led Mills (*c.g.*⁸⁹) to erect an erroneous concept²⁸ of the action of tissue extracts in blood-clotting (cf. Smith *et al.*¹⁰⁹) "Denaturation" can be controlled by keeping blood cool and free from protein precipitants.⁶²

We have had preparations⁴⁴ apparently free from "lytic factors" (proteolytic enzymes of blood and tissue origin); and the alcohol-precipitated human fibrinogen prepared by Dr. R. M. Ferry at the Harvard Plasma Fractionation Laboratory¹⁹ is a refined product, all but enzyme-free. Apart from specific tests for such impurities as those mentioned as interesting to the "coagulationist," the physical chemist is checking the purification by the best modern methods¹²² such as solubility tests,¹⁷ electrophoretic analysis (Tiselius¹¹⁶) and ultracentrifugation (Svedberg¹¹¹).

Cataphoresis,^{110, 115} electrometric titration,⁹³ and flocculation maxima in *electrolyte-poor* buffer^{44, 83} agree in establishing the isoelectric point of fibrinogen at close to pH = 5.4. There is no pH shift during blood-clotting.^{23, 51} Modern applications of physical methods are excellently reviewed by Wöhlisch,¹¹⁸ the techniques including (1) ultramicroscopy (dark field), (2) optical polarization, including streaming double-refraction and depolarization of diffracted light (Tyndall-beam), (3) x-ray spectroscopy, (4) electron microscopy, (5) viscosimetry, including application of the principles of "humoral rheology,"²⁰ (6) orientation in surface films, (7) polarography, and (8) studies of hydrotropy (especially with urea). The major conclusion from these techniques is that both fibrinogen and fibrin exist in elongated (fibrillar) micelles with definite fluid and colloidal properties. In analyzing the data great caution is needed to avoid many pitfalls occasioned by the crude and impure materials. The effects, for instance, of traces of contaminating proteolytic enzymes repeatedly come up for comment.¹¹⁸

Prothrombin is the most difficult of all clotting agents to purify.⁷ Some highly potent materials are currently being prepared,^{86, 107} but our own experience with similar techniques affords abundant evidence that mere potency is no criterion of purity in the chemical sense.^{36, 41, 49} The best thrombin preparations^{4, 5, 87, 90, 105, 106} are purer, but few of them^{97, 105} succeed in eliminating a proteolytic contaminant which has all the characteristics of serum tryptase.^{50, 90} The cruder prothrombins keep poorly in solution³⁶ and are likely to pass over into thrombin "spontaneously," or under such simple physical treatment as acidification, dialysis, shaking with chloroform, and the like.⁹ Long experience with preparations which do not behave thus has convinced us of the soundness of the view that the elaboration of thrombin from its inactive precursor requires certain specific "activators."^{33, 35, 53, 54} The persistence of traces of these in the cruder prothrombin accounts for the phenomena cited.

Activators of Prothrombin.³¹ The first of these is ionized *calcium*, almost unique in this respect.³⁰ But we have frequently obtained prothrombins which were not at all (or very poorly) activated by calcium salts alone.^{33, 53} The second factor (or factors) needed has received a variety of "working names" such as *zymoplastic substance* (Schmidt), *thrombokinas* (Morawitz) or *thromboplastin* (Howell), but before analyzing the recent advances in the elucidation of the thromboplastic factors, we may add a few comments on the calcium story. It is the active Ca ion which is normally essential and it takes a considerable excess of oxalate, citrate, or other Ca-ion depressants, added a sufficient time before completion of the prothrombin conversion, to prevent demonstrable thrombin formation. Nordbö's work⁹⁴ clarifies the underlying physical chemistry in terms of the Ca-ion "activity," which is subject to special influences in the presence of the protein colloids. Fully-formed thrombin is active in the presence of considerable excess of oxalate, etc. and some purified thrombins have been prepared completely Ca-free.³³ There is, however, an interesting intermediary stage in prothrombin activation, in which the thrombin (up to a short time after the mixture has reached its maximal coagulant potency) can never-

theless be progressively inactivated by oxalate or citrate.^{29, 33} Re-addition of adequate ionized Ca restores the process of thrombin formation. These facts, together with the quantitative dependence of the thrombin yield upon the amount of ionizable calcium present, below a certain "optimum," clearly indicate a Ca-prothrombin intermediary complex in thrombin formation.^{33, 35} These experiments³³ were performed in the presence of abundant cephalin,²⁷ a phospho-lipid.^{68, 119}

While the physical chemistry⁸⁰ of the *phospholipid-factor* in blood-clotting needs further study and we know of no coagulation studies as between (1) α - and β -forms⁸ or (2) * serine- vs. ethanolamine-cephalins,⁶³ it has been known since the experiments of Howell⁷¹ and his pupils⁸⁵ that *cephalin* has a unique rôle and is a constant chemical constituent of crude aqueous (or alcoholic) tissue extracts of "thromboplastin."⁶ It is equally clear, however, that the pure phospholipid cannot account for *all* the prothrombin-activating potency of crude thromboplastin.⁵³ Howell speculated that cephalin became more active as the result of combination with proteins.^{72, 73} Some recent studies claim to have identified such alleged compounds^{14, 15, 16} and the data are deserving of consideration, but they need to be regarded very critically in the light of the following facts. It is to be expected from the physico-chemical properties of cephalin,^{12, 80} and the fact is confirmed by experiments in the author's laboratory,²⁵ that this phospholipid is *always* in firm combination with the proteins present, and one has but to add its solution to any blood or tissue protein preparation and test the ability to recover the P-lipid by extraction procedures, to be convinced of this finding. Moreover, our prothrombins which were not activated to thrombin by calcium, alone, were shown by chemical analysis to contain significant amounts of cephalin and other P-lipids.⁵⁴ This is true, also, of all plasma-, cell-, and tissue-preparations. When comparable amounts of pure cephalin were added to Ca-prothrombin, complete activation to a very stable thrombin took but a few minutes. The clots formed with a good fibrinogen were firm gels and showed no retraction or liquefaction in many days. Hence, in the complete absence of demonstrable enzyme (lytic) factor, there was no evidence that the activation of prothrombin to thrombin required more than the two chemically identified entities, Ca-ions and "free" cephalin.⁵⁴ Further studies³⁵ revealed the quantitative dependence of the amount of thrombin formed upon the proportion of cephalin added, below an "optimum," and as little as one in several millions of the pure P-lipid had significant thromboplastic effects. Potent thrombins have been prepared completely free from phosphorus.^{5, 72, 87} Thus, it is concluded that cephalin, like Ca, is a component of an "intermediary" *Ca-cephalin-prothrombin complex* appearing temporarily during thrombin formation.⁸⁵

The fact still remains that crude aqueous tissue extracts are more thromboplastic than their isolated P-lipids, and this was proved by extraction and quantitative comparison in the author's laboratory.³⁸ Another experimental difference is the ease with which prothrombin activation can be prevented by heparin (see below) when cephalin is used as the thromboplastic agent, as compared with crude tissue extracts.^{34, 38} The addition of one other pure chemical agent bridges these differences. This is the enzyme, crystalline (pancreatic) trypsin.^{24, 92} An optimal mixture of Ca-salt, cephalin, and crystalline trypsin⁵³ is a thromboplastic agent that closely imitates the so-called natural "thromboplastin" in essentially all the phenomena of *in vivo* injections and of artificial blood-clotting systems,^{38, 54} including correction (*in vitro*) of the coagulation defect in hemophilia.³⁷ It would appear, therefore, that trypsin-enzymes supply the "missing link" in our data with reference to the thromboplastic system.

In the cited review⁴⁹ are mentioned the chief data on the natural "trypsinases"⁹⁶ of blood and tissues and the experimental work on proteolytic enzymes in relation

* Current experiments (unpublished), in collaboration with Dr. J. Folch-Pi, show that *both* these (and other) P-lipids possess thromboplastic activity (J. H. F.).

to blood clotting.²² It may be repeated that *trypsin* digests, but does not clot, prothrombin-free fibrinogen. The enzyme *papain* does both, and the fibrin clots which it produces are indistinguishable under the microscope from those produced by enzyme-free thrombin.⁵⁷ Claims¹¹ for a true thrombin-like action of the simple chemical, *ninhydrin* (1, 2, 3-indantrione hydrate), are not substantiated.⁵⁷ Two "inhibitors" of trypsin actions, (1) heparin (see below)^{66, 70} and (2) the crystalline polypeptide first isolated by Northrop and Kunitz,⁹² retard and may prevent blood-clotting.⁴⁶

Lytic Phenomena. Not immediately germane to the processes of blood clotting, but of great significance in linking the commonly encountered lytic phenomena (e.g. *progressive* destruction of prothrombin,^{24, 42} thrombin,⁶⁵ fibrinogen,⁴⁷ and fibrin^{45, 95, 112}) with the ordinary protein-digesting actions of "tryptases,"⁹⁶ are recent correlations of these phenomena in natural (isolated) and purely chemical systems.^{65, 81} A practical result of such studies has been the development of sensitive and selective "assay" methods with which to detect and measure the natural tryptase enzymes. Timing the lysis of fibrin^{45, 48} or of fibrinogen,⁴⁷ in which "activated" tryptase unknowns are compared with a reference series of standard trypsin dilutions, are two such methods of wide applicability.

There is clear evidence that "active" tryptase is not normally present in the blood, which is indeed capable of *inhibiting* added trypsin.^{50, 78} It is necessary to free the enzyme from its naturally inactive state by such procedures as acidification, dialysis, or shaking with chloroform, etc.^{78, 95, 104, 112} (cf. "spontaneous" activation of prothrombin⁹). It is not yet certain whether these procedures (especially the last) can be relied upon quantitatively, but they do, at least, have possibilities.^{45, 47, 114}

It should be of particular interest to the colloid chemist to attempt an explanation of the exact way in which tryptase "activation" occurs in shed blood and with special reference to the cited procedures. At present we can only theorize that "wetting" (contact with foreign surfaces) and the whole set of conditions encountered *in vitro* may introduce new conditions favorable to activation of the enzyme, perhaps by releasing the system from some "stabilizer" (in the colloid sense).⁹⁸ A plausible analogy is the autolysis of damaged tissue cells by their cathepsins (proteolytic enzymes) when they are "damaged" by withdrawal from their natural environment and subjection to various traumatizing conditions. If Schmitz¹⁰⁴ is correct in postulating not only an inhibitor-combination, but also an inactive precursor form ("tryptogen"⁴⁹) for the plasma tryptase, analogies may be drawn between the blood enzyme system and that so clearly worked out by Northrop and his colleagues for the pancreatic trypsins.⁹² The blood tryptase, however, is not dependent upon the pancreatic secretion¹¹³ nor is it related to the digestive cycle (author's unpublished experiments). That *tryptogen* activation proceeds "auto-catalytically" is suggested by some recent experiments in the author's laboratory, the data indicating a close parallelism between enzyme liberation and actual clotting.⁵⁰

Clot Inhibition. The field of clot inhibitors is too extensive to cover in this review, but the major facts relating to the heparins are included in recent articles on this topic.^{56, 70} The Ferguson clotting theory⁴⁹ attributes the normal fluidity of the blood to the absence of enzyme catalysts of the thromboplastic system. In part, at least, such absence may be due to the demonstrable tryptase-inhibitors of plasma (and serum). *Heparins*, which are now believed to be mucoitin-polysulfuric esters⁷⁹ derived from the metachromatic (toluidin-blue-staining) granules of the Ehrlich mast-cells (basophils),¹¹⁷ may very well appear in the blood as the result of dissociation of protein combinations of varying potency (Jaques).^{76, 77} It is possible that these heparins or their protein combinations are the anti-enzymes⁶⁶ and anti-coagulants⁶⁷ we are looking for. It should be mentioned that in artificial clotting-systems heparin requires a *co-factor*,⁷⁴ which has so far been but partly identified as a component of certain plasma albumin fractions.^{18, 120} As to the mode

whereby heparin (or heparin *plus* co-factor) inhibits clotting,³ mention will merely be made of three experimentally demonstrated reactions: (1) "anti-thromboplastic," which may be due partly to displacement of cephalin^{12, 34} and partly to inhibition of tryptase enzyme;^{40, 55} (2) "anti-prothrombic," by which we indicate such results as show a lessening of the thrombin yield;⁵⁵ and (3) "anti-thrombic," *i.e.*, interfering with the final thrombin-fibrinogen reaction.^{67, 108} These actions are initiated, in whole or in part, by numerous other chemical agents^{40, 67} and they undoubtedly have a common physicochemical basis^{58, 61} which can be summed up in terms of the colloidal properties of the proteins involved, including the enzyme-proteins as well as their substrates.

In summary, the author's view of the coagulation phenomena is as follows: Blood plasma contains all the necessary factors for clotting, but some of them are not normally in "available" form because the whole unit has the characteristics of a "stabilized colloidal system."^{59, 98} We can definitely point to inhibition of tryptase enzymes in this natural system and can demonstrate the enzyme by appropriate activation procedures. It is, therefore, believed that, with the removal of colloidal "protectors" during the physicochemical disturbances attending blood shedding, or damaging of the blood vessels *in vivo*, new conditions result in the appearance of active enzyme. This catalyzes the formation of thrombin from prothrombin via an "intermediary" complex containing prothrombin, calcium, and cephalin. The final thrombin is enzyme-like in potency and in the kinetics of its interaction with fibrinogen to form fibrin. It would be interesting to attempt a more modern comparison (cf.¹⁰³) of this reaction with other crystalline gels, forming from sol precursors under the influence of small amounts of initiating agents.

Thrombin itself is not proteolytic in the ordinary sense, but continuing action of the serum protease may result in the variable and incidental accompaniments of blood coagulation, (1) thrombinolysis (progressive "antithrombic" action), (2) fibrinolysis, and its preliminary, "clot-retraction," which may readily be explained as the digesting away (by tryptase) of the attachments of the fibrin threads, thus permitting elastic retraction from the stretched state in which they are deposited. This clotting theory incorporates all the major features of earlier viewpoints and permits due interpretation of the newer facts, while still leaving room for supporting and supplementary data to be expected from the work to come. As this article constitutes a "progress report" rather than a strictly scientific review, the exigencies of space preclude full reference to the extensive experimental literature upon which the facts assembled are substantially based, but the appended bibliography may be consulted for a wealth of reference data in the specifically indicated fields.

Immunology *

WILLIAM C. BOYD

Evans Memorial and Mass. Memorial Hospitals, School of Medicine,
Boston University

Progress in the science of immunology has been so rapid in recent years that a large part of the subject can now be treated purely from the point of view of the chemist. This is mainly due to the preponderant role in immunity of the defensive substances—*antibodies*—produced by an animal in response to the entrance of certain foreign chemical substances, called *antigens*. Writing primarily as a chemist, the present author will therefore limit this article arbitrarily to a consideration of antibodies, antigens, and the nature of the reactions which take place between them.

Antibodies

Since antibodies were originally purely hypothetical substances, they were named and characterized according to their effects. Just as there was a period in science when a group of chemists and physicists decided to dispense with the (then unprovable) atomic theory, and to deal solely with observable phenomena—a point of view which has turned up again in different guise in quantum mechanics—so in the development of immunology there was a period when many workers wondered if it would not be better to speak, not of “antibodies,” but of “a modification of the physical state of the serum,” so as to give it antibody properties, being careful to avoid making assumptions as to the cause or nature of this modification. We now know that antibodies are actual chemical substances (modified globulins), and we can give up this excessive caution and, on the basis of modern knowledge, begin our discussion of antibodies immediately.

Specificity of Antibodies. An antibody produced in response to one pathogenic organism, A, will generally not protect against, or otherwise react with, organism B, and *vice versa*, unless the two are closely related. This fact, among others, is one of those leading us to speak of the specificity of antibodies.

The specificity of serological reactions, extraordinarily sharp, but still limited, has been well defined by Landsteiner⁷³ as “the disproportional action of a number of similar agents on a variety of related substrata.” This definition seems the best that has been proposed, although it would also include many chemical reactions, as might be expected if serological specificity were fundamentally chemical in its nature.

The specificity of antibodies has been explored in great detail by numerous workers in the present century, notably by Landsteiner.⁷³ The work has been done in part by the study of reactions with related natural proteins, but largely by the

* Thanks are due to the Interscience Publishers for permission to make use of material which formed part of the author's “Fundamentals of Immunology,” New York, 1943.

use of "conjugated antigens." By the term "conjugated antigen" we mean an antigen which has had a new specificity grafted onto it by chemical treatment. It has thus been possible to create new categories of specificity, so that a chemically conjugated protein will engender antibodies which will react with other unrelated proteins similarly treated. Methods of doing this are discussed in the various papers devoted to the subject.

The great significance of Landsteiner's work on artificial antigens was to show that antibodies could be directed toward relatively small, well-defined chemical groups on an antigen, instead of toward the whole molecule, and *could react with these groupings separately*. From the chemist's point of view, this is probably the greatest single step forward yet taken in the study of immunology, since it advanced the science at once from the stage where an unknown, special constitution, peculiar to proteins, was thought to be necessary to incite the production of antibodies, to the stage where the chemical composition of the groups determining antibody production and antibody reactivity could be studied.

Study of synthetic, artificial antigens has shown that antibodies produced by them may be of several sorts. In the first place, especially if the chemical treatment has not been too drastic, the serum of an animal immunized with such a treated protein may contain antibodies directed towards the protein substrate, having no relation to the new specificity. It may contain antibodies directed chiefly towards the introduced groups, or towards these groups and the parts of the protein molecule with which they combine. Also, antibodies may occasionally be found which are directed simultaneously towards the original protein and the introduced group.^{53, 51, 86}

If we study only the antibodies directed towards the introduced chemical group (hapten), we may still find that although in some cases the specificity seems complete, *i.e.*, the immune serum reacts only with the homologous antigen, more frequently cross reactions are found, even though the reactions with the homologous antigen are most intense. In other words, the immunological mechanism is not able to distinguish absolutely between very closely related compounds. We may suppose that the antibodies, although they reflect in some way the characteristic electronic pattern of the antigen or hapten, do not reflect every detail perfectly. There will be some blurring of outlines. Or we might change the metaphor, and say that antibody is a lock fitted by the hapten; the lock, however, is of somewhat simpler construction than the key, so that keys for other locks may also open it, though perhaps not so readily.

Experiments further indicate that a large number of serologically different compounds could be made up from amino acids, in conformity with the large numbers of specificities found in natural proteins. They indicate that the antibody-forming mechanism can recognize as a unit a fairly large chemical compound. Just how large a group can still be responded to as a whole is not known; the maximum must be smaller than the surface of the smallest protein molecules, but probably larger than any synthetic compound yet studied.

Nevertheless, the immunological mechanism can on occasion single out parts even of chemical compounds of moderate size, so that the specificity in some cases is chiefly or solely directed towards one part of the molecule.

The differences observed in antibodies to aromatic compounds containing the same substituents, but in different positions, indicate that the spatial arrangement of groups, as well as their chemical nature, is of importance in immunology. This conforms to our earlier knowledge of other aspects of biological chemistry, where spatial arrangement is known to be important. For example, enzymes, as is well known, have frequently been found to be specific for one of the stereo-isomers of a substance, different isomers of optically active dyes have been found to have different staining effects, optical isomers of some of the amino acids have different tastes, and optical isomers of drugs usually exhibit different potencies.

Chemical nature of antibodies. Antibodies are serum proteins, with physical properties indicating that they belong in the "globulin" class. An antibody clearly must differ in some respect from the other globulins in the serum, since it bears the imprint of its characteristic specificity, not possessed by the others; this must reside in some chemical difference in at least part of the molecule. Nevertheless, no marked chemical or physical differences have been observed between antibodies and so-called "normal" globulins.

It has, however, been found that the antipneumococcus antibody in horse serum has an isoelectric point of about 4.8, while that of the normal horse globulin is 5.7.⁵⁹ Green, McKhann, Kapnick and Fahey⁴⁸ found that the water insoluble globulin from horse antipneumococcus sera has a viscosity different from any of the normal proteins, and its titration curve differed slightly from that of normal globulin. See also Goodner and Horsfall.⁴⁷ The antipneumococcal antibodies in horse serum have a much higher molecular weight than the majority of the horse serum globulins, but a small amount of a globulin with this molecular weight is also found in normal horse serum.

In contrast to the horse, the rabbit produces antibodies to the pneumococcus which have the same molecular weight as normal rabbit serum globulins.

There was probably at first a tendency on the part of certain immunologists to think and speak of antibodies as if their nature would be a function solely of the antigen towards which they were directed. This may have been easier because it was not yet fully established that the antibodies were themselves proteins. Since the serum proteins of different species exhibit chemical differences, it is to be expected *a priori* that their antibodies will also have different properties. This has been found to be the case. Aside from the difference just mentioned between the horse and rabbit antipneumococcus antibody in regard to molecular weight, it has been found⁷⁰ that all antipneumococcus antibodies so far examined fall into two groups as regards molecular weight. In the cow, horse, and pig a heavy molecule of molecular weight 990,000 is formed; in man, rabbit, and monkey, the molecular size is that of the normal serum globulin, about 160,000. On the other hand, horse anti-toxin (diphtheria) has only the normal molecular weight of serum globulin.⁹²

Goodner and Horsfall⁴⁶ observed a distribution of antibodies into two groups with respect to complement fixing ability and liquid composition. They found that complement (probably from the guinea pig) was fixed by antibodies from rabbit, rat, guinea pig, and sheep, whereas complement was not fixed by antibodies from horse, man, dog, mouse, cat, and goat. Dingle, Fothergill and Chandler²⁷ also observed similar differences. It will be observed that the above list does not quite correspond to the classification based on molecular weight. Boyd¹⁴ found indications that antibodies fall into two classes in regard to flocculative behavior.

The solubility behavior of antibodies is generally the same as that of the class of serum proteins to which they belong, but here too species differences are found. Rabbit antibodies to proteins seem generally to appear first in the fraction of the globulins precipitated in 13.5% sodium sulphate solution ("euglobulin"); then as immunization progresses, they are found also in the fraction precipitated between 13.5 and 17.4% ("pseudoglobulin I"); and only in powerful sera, as a rule, are they found in the fraction precipitated between 17.4 and 21.5% sodium sulphate concentration ("pseudoglobulin II").¹⁵ During immunization these globulin fractions in the rabbit tend to increase roughly in this order. In the horse, antibodies to toxins and other proteins tend to fall chiefly in the pseudoglobulin fraction, and the results of Reymann¹⁰⁰ suggest that in this animal it is this fraction which increases most on immunization.

Antitoxin in horse serum is usually found to some extent in all three globulin fractions, and variations in its distribution among the fractions are found, even in the sera of the same animal examined by the same method at different times.^{42, 79}

The findings depend partly on the method of protein precipitation used. In the goat it appears that diphtheria antitoxin has chiefly the properties of a euglobulin.⁶ Felton^{31, 32, 33} found the antipneumococcal antibodies in horse serum to be of euglobulin character, and on this fact based his widely used method of concentrating these antibodies.

It is a noteworthy observation that immune antibodies, at any rate, are never found in the albumin fraction of the serum in any species.

In their susceptibility to the action of various denaturing and destructive agents, antibodies closely resemble proteins in general. A good summary of their reactions will be found in Marrack's book.⁸⁵ They are destroyed by heat very much as proteins are denatured. In many instances the course is that of a monomolecular reaction, with a very high heat of activation, as in denaturation; probably the process is essentially just that. Antibodies are destroyed by alcohol, but in the cold, or if the alcohol concentration is brought rapidly to over 90%, this is much less marked. Treatment with protein-altering reagents, such as diazonium compounds, iodine, formaldehyde, and ketene, usually reduces or destroys the activity of antibodies.

Antibodies are destroyed by pepsin, less rapidly by trypsin. Note, however, that Parfentjev⁹³ found that treatment of diphtheria antitoxic serum with pepsin until 70-80% of the protein was rendered non-coagulable by heat, resulted in considerable purification, giving a product a high proportion of which was specifically antitoxic.^{94, 110}

The species differences between rabbit and horse antibody have recently acquired a practical aspect as the result of studies by Goodner and Horsfall,⁴⁷ and rabbit antipneumococcus serum has to some extent replaced horse serum for clinical use.

Neurath⁸⁹ has calculated that in a molecule of rabbit antipneumococcus antibody, the longer and shorter axes are in the ratio of 9.2, the shorter axis being 37 Å in length, and the longer axis 338 Å. For rabbit antibody the axis ratio is 7.5, and the lengths of the axes 37 and 274 Å. For horse antipneumococcus antibody these figures become 20.1, 47 Å and 950 Å.

The majority of antibodies which have been studied in the Tiselius apparatus have proved to be α globulins. Certain horse antisera, however, may show a component which migrates as a slow β (β_2) globulin. In some horse anti-diphtheria sera two sorts of antitoxin may be found, a β_2 , and a γ . They show definite differences in serological properties.

The electrophoretic mobilities of various purified antibodies and normal serum proteins have been determined by Tiselius and Kabat¹⁰⁶ and others. The results are shown in Table 1. It will be seen that the mobilities of the various normal components in the sera from the several animal species are approximately the same. In

Table 1. Electrophoretic Mobilities of the Components of Sera from Various Species (Modified from Tiselius and Kabat.¹⁰⁶)

| Species | Antibody for | ab $N/\Sigma N$ (%) | Al | $\mu \times 10^6 \text{cm}^2 \text{sec}^{-1} \text{volt}^{-1}$ α | β | Ab | γ |
|---------------------|---------------------|------------------------|------|--|---------|------|----------|
| horse ¹ | pneumococcus type 1 | 20.7 | -5.5 | -3.7 | -3.0 | -2.1 | -0.9 |
| horse ¹ | pneumococcus type 1 | 21.8 | -5.7 | -4.0 | -3.2 | -2.2 | -1.3 |
| horse ¹ | — ⁴ | 0 | -5.7 | -3.8 | -3.1 | .. | -1.0 |

³ At pH 7.3.⁹⁰

⁴ Normal horse serum.

α , β , γ = globulin fractions. Al = albumin. Ab = (special) antibody component.

the pig, rabbit, and monkey (in which it has been found that the antibodies have the same molecular weight as the γ globulin fraction) no new electrophoretic component was found, but in the horse a new component, between the β and γ components, appeared. This new component seems to be all antibody, since it is absent from the same serum after the antibody has been removed by "absorption" with antigen. This serum showed in the ultracentrifuge a heavy component which was the bearer of the antibody activity. Pig serum, which also possessed such a heavy component, did not show the component with the new electrophoretic mobility at pH 7.72, but did at another pH.

There have been a number of analyses for nitrogen, amid nitrogen, mono-amino, and di-amino nitrogen and amino acids in antibodies, and also in specific precipitates containing a non-nitrogenous antigen. On the whole, the differences between samples, and between antibody and normal globulin, do not seem to be greater than could be accounted for by the use of different methods by different workers.

Valence of antibodies. It is common to speak of a polyvalent serum, meaning one which contains antibodies for more than one antigen, *e.g.*, against several types of pneumococcus. The antibodies in such sera are separate and distinct. There is another question of valence which is the one we wish to discuss here, namely, the number of specific combining groups on a single molecule of antibody.

It is hardly likely that the specific reactivity of an antibody molecule could be distributed uniformly over the whole surface. Also, either of the theories of antibody formation now considered tenable^{1, 96} could lead us to predict that a molecule of antibody could not have many more than two localized reactive groups. What we know of specificity shows that orientation in space is important, and the combining group of an antibody must therefore possess spatial differentiation.

It has been found^{99, 36} that when slides are coated with a film of antibody *ca.* 45 Å thick, antigen can be specifically deposited, on top of this another film of antibody, and finally another film of antigen. If the antibody molecules are all oriented alike in such films, this would seem to demonstrate that the antibody is at least divalent. However a colleague has pointed out that it is perhaps not excluded that each film might consist of molecules arranged alternately up and down, in a head-tails-head-tails . . . arrangement, so that even antibody possessing only one reactive site per molecule might still give the "sandwich effect."

It has been observed in a number of cases^{55, 91, 60} that there may be present in a serum, antibody which has the power of combining with antigen, but does not form a precipitate. Such antibody has been variously referred to as low grade, incomplete, imperfect. Heideberger⁵² calls it "univalent," but states elsewhere⁶⁰ that the word "univalent" is not used in the literal sense. The special properties of this antibody may perhaps be due to imperfect specificity, or physical properties different from those of "good" or "polyvalent" antibody, or both.

There is one theory of antigen-antibody reactions which necessarily supposes the antibodies to be polyvalent or at least divalent, but since we cannot regard this theory as completely established, the polyvalency of antibodies cannot be considered proved. The proper way to settle the point seems to be a study of the molecular composition of antigen-antibody compounds made with excess antigen. Pauling⁹⁶ has proposed the determination of the valence of antibodies by analysis of precipitates of antibody and a synthetic conjugated antigen. From certain data of Haurowitz, Kraus and Marx,⁵¹ which led these authors to conclude that the antibody was monovalent, Pauling concludes that it was probably divalent. Such studies apparently have not so far revealed any compound containing more than two molecules of antigen in combination with one of antibody, so that the maximal valence so far found for antibody is two. Antigen, on the other hand, is almost always multivalent, and compounds have been observed in which over 100 molecules of antibody were combined with one of antigen.⁶⁶

The only experimental work directed precisely at the investigation of the valence of antibodies is that of Haurowitz and collaborators.^{51a, 51b} These results suggest that antibodies do not have a valence greater than one.

Antigens

Conditions of antigenicity. A very large number of substances have been investigated for their antigenic power, and it is natural to consider them as a group and try to see what characteristics they have in common. Unfortunately the knowledge which has thus been acquired is very meager; we are not yet able to say, from the chemical properties of a substance, that it will *certainly* be antigenic or non-antigenic. However, certain general principles do emerge.

(1). Antigenic substances are always large molecules, of molecular weight of the order of 10,000 or higher (excluding simple compounds which have been found to *sensitize*) and consequently are usually colloidal in solution. Correlated with the large molecular size is the inability of antigenic substances to go through collodion or cellophane membranes which pass smaller molecules such as sugar. There is some indication that in general the larger the molecules the better the antigenic power.

Another indication of the importance of particle size in antigenicity is the fact that non-antigenic or weakly antigenic substances can sometimes be made antigenic by adsorbing them on particulate matter such as collodion particles, kaolin, or charcoal.^{45, 75, 98, 108}

(2). The majority of antigenic substances are proteins, and it was formerly believed that only proteins could act as antigens. It has since been found that some "lipoids," when mixed with antigenic protein and injected, produce antibodies. Further than this, it has been found that some carbohydrates (usually of bacterial origin) and lipoid-carbohydrate compounds, even when carefully purified to remove protein, will produce antibodies when injected.^{34, 5, 38, 35, 90} In some cases these latter classes of substances are inferior to proteins as antibody producers.

Aside from these three classes of substances, it has not been certainly established that any other class of compound can be antigenic.

Not all proteins are equally good antigens. Here, and in much that follows, we mean "antigens for rabbits," for this is the animal most often used; some species seem definitely inferior to the rabbit as precipitin producers. Even within this species, individual differences may be found in antibody producing power for a given antigen. The best antigens are probably complex mixtures, such as whole blood serum, or bacteria or blood cells. Then probably come certain proteins, such as hemocyanins, ovalbumins. Hemoglobin is a poor antigen, and has in fact several times been erroneously reported to be non-antigenic. Finally gelatin (a derived protein) is non-antigenic, except as a conjugate. The simplest proteins, the prolamines, are also non-antigenic.¹¹¹

(3). As a rule the proteins of an animal are not antigenic for itself, or for another individual of the same species. In immunology this principle has received the name of *horror auto!oxicus*, which is stated thus: an animal will never produce antibodies to any substance normally found in its own circulation.

Some workers apparently believe that antibodies to an individual's own antigens may be produced, but never observed, since they would be continually removed by combination with the big excess of the antigen constantly present. Others feel that this violates some sort of "principle of laziness" in nature and that such antibodies are probably not produced at all.

The qualification which restricts the principle to substances in the circulation is needed, for it has been found that protein from the lens of the eye ^{cf. 111} will produce antibodies in the same species,^{cf. 72, 84} and it has been claimed ^{cf. 81} that a guinea pig can be sensitized with the lens of one eye and later shocked anaphylactically with the

lens of the other. Lewis⁸¹ found that lactating goats could be caused to form antibodies to their own casein; these antibodies reacted to an equal degree with cow casein. Hektoen (cited by Lewis⁸¹) reported obtaining other *iso-antibodies* in rabbits, against thyroglobulin (the iodine-containing protein of the thyroid gland) and fibrinogen from the blood. Stokinger and Heidelberger¹⁰³ however, found definite differences in their antisera to thyroglobulin from man, hog, cow, and sheep. Thus it seems established that certain proteins of the body, which never normally come into the circulation, can act as *iso-antigens*.

In general we may venture to surmise: (1) the antigenic power of the proteins is greater the more removed is their source from the experimental animal in the zoological scale; (2) very simple proteins are not antigenic. These guesses may not be wholly correct, of course. Plant proteins seem in general good antigens for animals, although perhaps not as much better than animal proteins as their greater taxonomic remoteness would suggest.

Gelatin contains no tyrosine or tryptophane, and but little phenylalanine. The fact that it is not antigenic led Obermeyer and Pick^{cf. 73} and Wells¹¹¹ to infer that the aromatic radicals of the protein molecule are of importance in determining antigenic activity. In support of this idea Wells mentioned several facts, among them the observation of Obermeyer and Pick that chemical substitution in the tyrosine nucleus markedly alters the immunological specificity of proteins. It is difficult to test this idea, but there are some observations rather contrary to it.

In the first place, it has since been found that substitution in other parts of the protein molecule also alters the specificity. Aromatic groups can be introduced into gelatin without making it antigenic.⁶⁷ Landsteiner points out that not all proteins possessing aromatic groups are antigenic; examples of this are proteins which have been altered sufficiently by acid or alkali. In other experiments^{62, 22} introduced aromatic groups did make gelatin feebly antigenic. Hooker and Boyd concluded that their experiment did not show that the non-antigenicity of gelatin was due solely to its deficiency in aromatic amino acids, since the possibility that non-aromatic prosthetic groups, especially if they contained polar groups, might also make gelatin antigenic had not been tested.

Some carbohydrates, not possessing aromatic nuclei, are nevertheless somewhat antigenic. The power to immunize seems to depend on general properties of the molecule; or perhaps, though this is much less likely, on some specific characteristic as yet unknown to us which antigens have in common; the possession of aromatic groups does not appear to be one of these characteristics.

Finally, Landsteiner's observations that simple substances not causing antibody formation, and not necessarily containing aromatic groups, can still react specifically with antibodies, were rather against the idea, which was partly based on the notion that antigenic capacity and ability to react with antibodies were inseparable.

When proteins are racemized by treatment with alkali, they are no longer antigenic. Since it was found by Dakin and Dudley²⁴ that such proteins were no longer susceptible to hydrolysis by enzymes, it was suggested that these facts were causally related.¹⁰⁵ This suggestion recalls the "digestion" hypothesis of antibody formation. However other workers have more recently found⁸² that these racemized proteins are not completely resistant to enzyme action. It has also been found that the antigenicity is lost more rapidly than the optical activity.¹¹⁴ Landsteiner⁷³ has pointed out that the alkali might destroy structures significant for the antigenic function at the same time that it produced racemization. Another explanation for the lower antigenicity of alkali-treated proteins may be smaller molecular size. Boyd¹² found that on treatment of crystalline ovalbumin with alkali there was at first a marked rise in optical activity to several times the initial value, followed by a slower fall to a minimum, indicating possibly that the molecule was first split, then racemized.

That racemization does not in itself mean non-antigenicity is indicated by the

observation of Landsteiner and Barron⁷⁴ that nitration of racemized proteins restored some antigenicity, as, to a lesser degree, did iodination.⁶⁹

There seems to be no proof, therefore, that optical activity is essential to antigenicity, although it may play an important role in specificity.

The specificity of antigens. The specificity of antigens resides in the structural peculiarities of their molecules. While it has not been possible to correlate immunological differences in substances, particularly proteins, with their chemical structure in every case, there is no doubt that this failure is due simply to our ignorance of the detailed structure of these compounds.

The dependence of specificity on chemical structure is proved by several lines of evidence. (a) Purified proteins that exhibit chemical differences can nearly always be differentiated serologically.^{111, 26, 49, 25, 63, 76, 57} (b) Carbohydrates related structurally give serological cross reactions.^{4, 44, 43} (c) Simple chemical substances (haptens) give cross reactions when chemically similar.⁷³ (d) Chemical alteration of antigens generally alters their specificity. (e) Corresponding proteins of different species which are functionally, and thus probably structurally, related, generally cross react.

Antibody-Antigen Reactions

General characteristics. The majority of those actively engaged in studying immunological reactions are convinced that the reaction between antibody and antigen is a chemical reaction. Certain difficulties have arisen in attempting to interpret all the observations in a consistent way, probably because of the size and complexity of the molecules involved. The reaction between antibody and antigen, and the reaction between proteins and proteolytic enzymes, are the only instances which have been well studied of reactions occurring between molecules of very large size; it need not be surprising if some new features emerge. We omit discussion of the reaction with haptens, which are usually much smaller molecules, and reactions with intact cells such as bacteria or erythrocytes.

Several salient characteristics of the reaction may be mentioned:

(1). The reaction is specific. This point has already been discussed, and it will not be necessary to give examples here. We should keep in mind the specificity of the reaction when we speculate on the mechanism of union, that is, the nature of the forces holding antibody and antigen together.

(2). The *entire* molecule reacts, not some fragment split off from it. This is clearly shown by the ultracentrifugal experiments such as those of Heidelberger and Pederson,⁵⁸ and of Pappenheimer, Lundgren and Williams.⁹²

(3). The antibody molecule, and molecules of protein antigens, at any rate, behave in these reactions as fairly rigid *ellipsoids* of greater or lesser eccentricity. This is obvious if we accept the views of Neurath⁸⁹ on the shape of protein molecules. Boyd and Hooker^{16, 17} found that the composition of antibody precipitates is compatible with the idea that antigen molecules are roughly spherical and antibody molecules behave as elongated units, such as ellipsoids, or chains of connected spheres. It is also found in antibody-antigen reactions between films of the reagents⁹⁹ that the thickness (30 — 50 Å) of the films is such as to suggest that the molecules are behaving like ellipsoids. Rothen and Landsteiner¹⁰¹ found that thinner (9 Å) films of antibody would no longer react specifically, suggesting that antibody no longer exhibits its specific behavior if it loses its globular shape.

Evidence that protein molecules act as fairly rigid spheres or ellipsoids comes from their behavior in intense gravitational fields¹⁰⁴ and their possession of a definite electric moment.¹¹⁵

Certain earlier workers apparently supposed that the antibody spread as a film over the surface of the antigen. Such a film would resemble a condensed protein

film, and having the polar groups turned away from the water, would account for the hydrophobic character of the compound.

Modern evidence however indicates that antibody does not behave as such a film. Also, the amount of antibody observed to combine with a molecule of antigen does not correspond to a film approximately 10 Å, as this would lead us to suppose, but to a thickness of about 30 Å. The electrokinetic properties of the antibody-antigen complex are still those of protein, and do not suggest that all the polar groups are turned away from the surface.

(4). *No splitting, digestion, or other profound chemical alteration takes place in the reacting molecules after they have combined.*

There are numerous observations showing that no profound alteration takes place in the antigen and antibody molecules after they combine. It is a well known fact that toxin is not permanently detoxified, but simply neutralized, by combination with antitoxin, and illness has resulted from the injection of originally neutral toxin-antitoxin mixtures in which the anti-toxin has been damaged or destroyed, as by freezing. Similarly, various workers have been able to recover unaltered antibody from antibody-antigen precipitates or "agglutinates."

It is evident that if any alteration takes place, it is reversible.²¹ A number of workers have thought that the antibody is denatured after combination with antigen. Probably without fully sharing this idea, Eagle²⁸ and Mudd^{cf. 87} have emphasized the similarity in properties of combined antibody and denatured globulin. This similarity certainly exists, and is probably significant for theories of serological reactions, but it need not mean that the antibody is actually denatured. Eagle suggests that it is due to the (assumed) turning of the polar groups of the antibody towards the polar groups of the antigen, leaving a surface composed predominantly of non-polar groups, with a consequent reduction of solubility in polar solvents.

Completely denatured proteins are found to have reverted to the fibrous form, which may be detected by x-ray analysis; therefore Marrack⁸⁵ points out that if the antibody in specific precipitates were completely denatured, this should be detectable by x-ray study, but actually experiments have not produced any evidence that the antibody in such precipitates has changed from the globular form. We may therefore conclude that the antibody in such precipitates is not wholly denatured.

Not only is the antibody not immediately denatured, but it has been found¹³ that the solubility of ovalbumin-antiovalbumin precipitates in excess of antigen was not altered by storage. Since such resolution is a specific reaction, the result indicated that no progressive denaturation of either of the reagents had taken place during the time of storage.

There is other evidence that the serological specificity of the antigen and antibody is not altered by their combination. Precipitates will specifically sensitize animals to the antigen, and to the serum proteins of the animal from which the antibody was derived; non-precipitating (inhibition zone) compounds of antibody and antigen can be precipitated, after the lapse of an indefinite time, by the addition of more of the deficient reagent, or by the addition of a different antibody directed against either the antigen or the first antibody. This again indicates that no significant denaturation takes place.

(5). The combination of antibody and antigen takes place at the *surface* of the molecules. This follows from the third point discussed above. Also Marrack⁸⁵ has pointed out that no molecule larger than the lower fatty acids can pass between the constituent atoms of a protein molecule, in view of their known distances from each other. Evidence for the role of surface in serological reactions has already been mentioned; it has been stressed by Hooker.⁶¹ The experiments of Marrack and of Rothen and Landsteiner¹⁰¹ suggest that when the antibody molecule is unfolded, thus producing a new "surface," it loses its power of specific combination, and the experi-

ments of Porter and Pappenheimer⁹⁰ indicate that the reactive capacity of the anti-toxin molecule is restricted to a portion of its surface.

(6). The union between antibody and antigen is a *firm* one, but is at least partially reversible. It is well known that it is quite difficult to dissociate diphtheria antitoxin and toxin after their combination.^{cf. 92} It is possible to dissolve the precipitate formed by the conjugate protein arsanilic acid-azo-casein and its antibody by the addition of dilute alkali; addition of dilute acid to this solution, which would not precipitate the antibody alone, throws down the antibody and antigen together, with hardly a trace of antibody left in the supernatant fluid.¹² Studies on the heat of serological reactions¹⁸ indicate a considerable energy change, implying a rather firm combination.

Nevertheless, the reversibility of serological reactions is shown by several lines of evidence, such as dissociation of antibody from precipitates and agglutinated cells, **solution of precipitates in excess of antigen, etc.**

(7). *Both antibody and antigen* enter into the specific precipitate which is formed. There is now abundant evidence for this statement, but before the introduction of quantitative methods into immunology the question was sometimes debated.

(8). Antibody and antigen can combine in *varying proportions*. This is an obvious consequence of the multivalency of one or the other of its reagents, and has been shown by numerous analyses. In the light of what we know now it may seem surprising that it was ever doubted, yet it is precisely the failure to recognize the possibility of combination in different proportions which caused the early writers on antigen-antibody reactions so much difficulty. However, once it was realized that antigen or antibody, or possibly both, was multivalent, the observation that antibody-antigen compounds may vary in composition becomes quite understandable.

(9). Serological reactions display certain analogies with *colloidal* reactions. These similarities are so striking that they will be discussed later at greater length.

The two stages of serological reactions. It is customary to consider serological reactions as occurring in two stages. Such a subdivision should not be taken as necessarily implying that the two stages do not overlap, for it is quite likely that the second stage sets in before the first is entirely completed.

These two stages are: (A) the specific combination between specific groups of the antibody and corresponding groups of the antigen or hapten; (B) the secondary, visible reactions which may follow this, such as precipitation, agglutination, complement fixation, etc.

There are several features of these reactions which make it convenient for us to retain the concept of division into stages.

(1). The first stage proceeds without visible alteration, and can be detected only indirectly, while the second may be quite conspicuous and easily detected; (2) in the case of haptens no second stage follows at all; (3) under some conditions, as in the absence of salts, the first stage can take place but the second cannot; (4) their speeds are very unequal, the first stage being extremely rapid, and the second sometimes very slow; (5) the energy change seems to take place during the first stage, the second being accompanied by little energy change; (6) there is some evidence (see below) that the specificity of the second stage may be of a lower order than that of the first stage.

First Stage: Combination

(1). **Mode of combination between antibody and antigen.** Because of the chemical nature of serological specificity, it is logical to suppose that the union between antibody and antigen is a chemical one, due to combination of the specific reactive groups of the two reagents. This is supported by such facts as the power of simple chemical substances (haptens) to react with antibodies, and by the analogy with enzyme reactions, known to be chemical.

The principal question in this connection would appear to be: is the union solely due to Coulomb forces (attraction between positive and negative charges, *e.g.*, $-\text{NH}_3^+$ and $-\text{COO}^-$) or are other forces involved? This is a difficult problem and has not been satisfactorily solved. This fact should not be too surprising when it is realized that until rather recently chemists were quite unable to give any rational account of how coordinate compounds (such as compounds containing water of crystallization) were formed.

If the forces acting are Coulomb forces, we should suppose that the combination between antibody and antigen is chiefly or entirely due to attraction between amino and carboxyl groups. There are points in support of this idea, such as the rapidity of the primary reaction, and the strong influence of polar groups observed in studies of specificity. In particular the immunological equivalence of such groups as Cl and CH_3 and the acidic character of serologically reactive non-protein

antigens, such as the pneumococcal polysaccharides, are suggestive. Goebel and Hotchkiss⁴⁴ found that anti-pneumococcus horse sera of types 1, 3, and 8 gave vigorous precipitation with artificial antigens containing benzenecarboxylic and sulfonic acid radicals, which are quite unrelated in chemical constitution to the pneumococcus polysaccharides. Chow and Goebel²⁰ suggested that combination between the pneumococcus polysaccharides and the corresponding antibodies might be largely due to attraction between the ionized uronic acid groups, containing $-\text{COO}^-$, and the ionized amino groups, $-\text{NH}_3^+$, of the protein. In support of this idea, it was found that treatment of the antibody with formalin, which reacts with the amino groups, destroys the precipitating power of the antibody, and acetylation, also affecting the amino groups, is almost equally effective.

Landsteiner⁷³ lists in favor of the idea that such a mechanism, which he refers to as the formation of salt-like compounds, may operate, the following: the prominent influence of acid groups (see above), the change in specificity following esterification of aromatic acids or proteins, and the similarity of hemagglutination and hemolysis produced by serological agents and by colloidal inorganic acids.

It has been objected that such a simple mechanism could not account for the specificity of serological reactions, but this is perhaps not a necessary difficulty. If a number of amino and carboxyl groups in the antibody are concerned when one specific determinant group in the antigen reacts, the specificity might be due to the spatial arrangement of these groups. The weaker union observed with the related heterologous antigens could be explained by a failure of the oppositely charged groups to correspond perfectly in position.

It is however possible that other forces, such as those classified as secondary valence, might play a role in serological reactions. It does not seem likely that the covalent bond is concerned, for as Landsteiner says, ". . . in velocity and easy reversibility antigen-antibody reactions differ from those due to primary valences and resemble the formation of ionic and molecular compounds; and a strong argument against the assumption of covalent bonds is the fact that quite different substances, regardless of their chemical nature, are capable of reacting with antibodies all in like manner." It is likely that similar objections apply against the co-ordinate link, or semi-polar double bond.^{47, 95} Other types of bonds which may possibly play some role in serological reactions are dipole-dipole bonds, dipole-ion bonds,^{47, 50} and the hydrogen bond. The latter consists essentially of a hydrogen atom which is attracted simultaneously to two different atoms, as in salicylaldehyde. The hydrogen bond, which is thoroughly discussed by Pauling⁹⁵ appears to be one of the forces keeping proteins in their characteristic configurations. Pauling believes that the hydrogen bond will be found to have greater importance for physiology than

any other single structural feature. It may well figure importantly in serological reactions for, as Pauling says, "... the hydrogen bond is the only strong and directed intermolecular interaction which can come into operation quickly."

Other writers have mentioned cases of specificity which compare with serological reactions. Thus Landsteiner⁷³ calls attention to the very interesting examples of the reactions of Cu with the $\text{HO}-\overset{\textstyle |}{\text{C}}-\overset{\textstyle |}{\text{C}}=\text{NOH}$ and TI with $-\text{CO}-\text{CH}_2-\text{CO}-$, and the observations of Bergmann on the precipitation of proline with some peptides by rhodanilic acid, and the distinctly specific precipitation of glycine, the simplest amino acid, with potassium trioxalatochromiate $[\text{Cr}(\text{C}_2\text{O}_4)_3 \cdot 3\text{H}_2\text{O}]$. Erlenmeyer and Berger³⁰ have stressed the analogy with the forces in crystals, and have drawn attention to the immunological similarity of CH_2 , NH , and O , of CH_3 and halogen, (groups which are mutually replacable in crystals of certain substances), and of the correspondence of antigens made from

(corresponding with the isomorphism of the salts of H_3PO_4 and H_3AsO_4 , etc.).

Erlenmeyer and Berger have stressed the importance of local similarities in electric field, resulting from equality in number of valence electrons of an atom or part of a molecule. Marrack⁸⁵ has drawn attention to the analogy with certain cases of remarkably specific *adsorption* to crystal surfaces.* Thus methylene blue is adsorbed by diamond and not by graphite, succinic acid by graphite and not by diamond. The only difference between these two crystals is the spacing of the carbon atoms; it will be recalled that we have already found spatial arrangement to be highly important for specificity. The dye I (below) is adsorbed on the crystal faces of potash alum, while its isomer, II, is not.

* See paper by W. G. France in this volume. J. A.

Differences have even been found in the degree to which optical isomers are adsorbed. Thus the dextro and levo forms of the dye made from phenyl-(*p*-aminobenzoylamino)-acetic acid

and dimethyl aniline, have been found to be adsorbed unequally by wool. It is certainly by no means inconceivable that the reaction between antibody and antigen may be at least in part caused by the same forces which act in these cases. Immunologists, however, no longer consider these forces any less chemical than the forces holding sodium and chlorine ions together in a crystal of sodium chloride. As Langmuir⁷⁸ puts it, there is “. . . no fundamental distinction between chemical and physical forces.”*

(2). **Analogies with colloidal reactions.** Serological reactions have a number of points of similarity with many colloidal reactions, as was well brought out by Bordet.^{10, 11} A consideration of these analogies will be helpful in understanding antibody-antigen reactions.

One important similarity is the ability of the reagents to enter into composition in almost any number of varying proportions, depending upon the ratio in which they are brought together. This is in sharp contrast to the behavior of simple chemical agents, and is evidently in both cases a consequence of the large number of reactive groups possessed by one or both of the reagents. Thus in serological reactions we find, as in colloidal reactions, that if an excess of one reagent is added, much more of it will be combined with than would be necessary to exert its typical effect; but *not more in proportion* to the excess added. That is, as more reagent is added, the additional amount taken up begins to taper off, giving a curve which flattens out, like an adsorption isotherm.

The two sorts of reactions also resemble each other in the importance of electrolytes, which in each case have considerable effect on the rate of reaction and the stability of the reagents. In both cases it may be found that without electrolytes the reaction does not go, at least to the extent of producing a visible change. The electrolyte concentration is also sometimes observed to have an important effect on the composition of the product which is formed. We may suppose that the effect of electrolytes depends in both cases on the important role played by electrical charges in the stability and reactivity of the substances.

The slow or imperfect reversibility of the reaction is also characteristic. It is well known that time is required for attainment of many colloidal equilibria, and that if an excess of one agent is added, the supersaturated compound which is formed is often only slowly converted to a compound of more “normal” composition when a corresponding amount of the second reagent is added. This is extremely reminiscent of the “Danysz phenomenon” in toxin-antitoxin reactions.

The effect of temperature, which may in some cases markedly diminish the amount of product or prevent its appearing, is also analogous.

Just as colloids often precipitate each other, antibody and antigen when mixed often produce a precipitate. The colloidal particles usually carry charges of opposite sign, which is not the case with antibody and antigen, though colloidal particles of the same sign may also combine.³⁹ Most striking of all is the fact that in both cases there is usually an “optimal” proportion in which the two reagents precipitate each other most rapidly and completely; if an excess of a certain one, or sometimes of either, reagent is used, precipitation is diminished, or absent. A good illustration

* See also Langmuir's paper in Vol. I, p. 525 *et seq.* J. A.

of this is seen in the reaction between ferric oxide sol and arsenious sulphide sol (Table 2).

Table 2. Flocculation of an As_2S_3 sol by a Fe_2O_3 sol⁷

| Total vol. 10 cc mg Fe_2O_3 | mg As_2O_3 | Degree of precipitation | Charge on particles in suspension |
|--|----------------------------|----------------------------|--------------------------------------|
| 0.61 | 20.3 | cloudy | — |
| 6.08 | 16.6 | immediate, partial | — |
| 9.12 | 14.5 | nearly complete | |
| 15.2 | 10.4 | immediate, partial | + |
| 24.3 | 4.14 | delayed clouding | + |
| 27.4 | 2.07 | none | |

The Fe_2O_3 particles are positively charged, the As_2S_3 particles negatively.

It will be noted that a well defined optimum, quite similar to those observed in some serological reactions, is obtained. In this case it evidently occurs at the point where the charge on the particles resulting from union of the two oppositely charged colloids is at a minimum; the reduction in the electrical repulsive forces allows the particles to approach each other closely enough to stick together. There are ways in which serological reactions may differ from this.

Second Stage of Serological Reactions (Neutralization, Complement Fixation, Precipitation, etc.)

When antibody reacts with simple haptens usually no second stage is observable, and it is likely that the primary stage of combination is the whole extent of the reaction. When toxins react with antitoxins, the toxic property is found to be wholly or partially neutralized. The combination of toxin and antitoxin *in vitro* is sometimes followed by another, visible phenomenon, and the combination of antibody with proteins, carbohydrates, and bacterial and other cells usually is. In spite of rather extensive study, the exact mechanism of these secondary reactions is still a matter of spirited controversy. The attempt here will be to present the facts, leaving controversy for other publications.

(1). **Toxin-antitoxin reactions.** These were among the first examples of immunological reactions to be studied, because of their practical importance, and the ease of determining the end point by test for toxicity on animals. We may consider them here as examples of serological reactions in which the first stage and second stage are probably one and the same, and consequently the reaction is particularly simple.

In the process of neutralizing toxins, antibody combines with them, in varying proportions, dependent on the ratio in which the reagents are mixed. Erlich early demonstrated that an antibody to the vegetable toxin, ricin, would neutralize *in vitro* its hemolytic power. Similarly it has been found that neutralizing antibodies for vaccinia virus can be adsorbed by the elementary bodies,¹⁰² which points to union between the virus and the antibody.

It is not known how the combination of antibody with toxins and viruses neutralizes them. Toxins are evidently not permanently changed by combination with antitoxin, for it has been found that diphtheria toxin, for instance, can be recovered from the combination by destroying the antitoxin.^{19, 109} Similarly it has been shown by Todd,¹⁰⁷ Andrewes,² and others that neutral mixtures of antibody and virus can in some cases be made active again by simple dilution or centrifugation. Perhaps the action of the antibody is simply to cover the toxin or virus and thus prevent it from coming in contact with the susceptible tissue. Salaman¹⁰² suggests that antiviral antibodies act by preventing the entry of the virus into the cell.

The quantitative course of such reactions was studied by Arrhenius. He assumed that the mass law was applicable. In its simplest form, however,

$$\frac{(\text{free toxin}) (\text{free antitoxin})}{(\text{toxin-antitoxin compound})} = K$$

(the parentheses indicate concentrations of the respective substances) this formula does not apply, so Arrhenius³ assumed that the reaction took place according to the following equation:

that is, that the reaction of one molecule of antitoxin with one of toxin gave two molecules of product. This led to the following relation:

$$\frac{(\text{free toxin}) (\text{free antitoxin})}{(\text{toxin-antitoxin})^2} = K$$

The values of q shown in Table 3 were calculated from this, assigning K the

Table 3. Observed Toxicity (q) of Tetanolysin after Addition of n cc of Antilysin, Showing also q Calculated in Various Ways

value of 0.115, and assuming that 0.276 cc of the antitoxin was equivalent to the quantity of toxin used. Arrhenius considered that the numerical agreement proved that the assumptions were correct, but his formulation is really in error in two respects. Toxin and antitoxin combine in more than one proportion, instead of giving only a single type of compound as Arrhenius assumed, and a molecule of toxin and one of antitoxin give only one, not two molecules of product. The agreement between the observed and calculated values of q is therefore fortuitous.

Since toxins and antitoxins combine in multiple proportions, the above simple mass law expression is not applicable, and we must assume a set of equilibria of the type

$$\frac{(A) (A_{n-1}G)}{(A_n G)} = k \qquad \frac{(A) (A_{n-2}G)}{(A_{n-1}G)} = k' \qquad \frac{(A) (A_{n-3}G)}{(A_{n-2}G)} = k'' \text{ etc.}$$

where A = antibody, G = antigen, and A_nG , $A_{n-1}G$ etc., represent compounds of antibody and antigen in various proportions. It can be shown that if $k = k' = k'' = \dots$ and a molecule of antibody occupies one combining site on the antigen, the quantitative relation between combined antitoxin and free antitoxin, or between combined and free toxin, will reduce to the Langmuir "adsorption" isotherm

$$R = nkx (1 + kx)$$

where R = the amount of antibody combining with a fixed amount of antigen (or vice versa), n and k are constants, and x is the final concentration.

Kinetically this amounts to assuming that antibody combines reversibly with a limited number of points on the surface of the antigen, which points are all alike for our purposes.^{82, 88}

The results of many experimenters^{29, 23, 8, 40, 41, 80} can be fitted by equations of the adsorption type. One of the most used has been the "Freundlich" adsorption isotherm

$$R = kx^n$$

where R is the amount of substance adsorbed per unit of adsorbent, x is the final concentration of the adsorbed substance in the supernatant, and k and n are constants. The Langmuir⁷⁷ equation is perhaps somewhat to be preferred since it can be derived from statistical mechanical considerations, without any reference to the mechanism of the reaction,³⁷ and would thus be expected to apply, allowing for its somewhat oversimplified character, to any action taking place reversibly at a surface where many combining sites are present.

(2). **The precipitin reaction.** The formation of a precipitate when antibody and soluble antigen are mixed is one of the most striking phenomena of serological reactions; the recent studies of it have yielded results of great interest and importance.

It has been found convenient to divide the whole range of the reaction of rabbit precipitin with antigen into the following five zones in order of increasing antibody and antigen ratio: complete inhibition, partial inhibition, antigen excess, equivalence, antibody excess. In the case of horse anti-protein precipitin it would be necessary to add two more zones, partial antibody inhibition, and complete antibody inhibition. The meaning of these terms will become clear in the following pages. A schematic

presentation of this arrangement, which also serves to indicate approximately the meaning to be attributed to each term, is given in Figures 1a and 1b.

Amount of precipitate: zones. Either the amount of antiserum or the amount of antigen can be varied; it is usual to keep the concentration of one reagent constant, and add different amounts of the other. Precipitates are now usually analyzed by some modification of the micro-Kjeldahl technic employed by Parnas and Wagner.⁹⁴ From the results so obtained we can calculate back to the basis of constant amounts of serum or of antigen. A series of such determinations made with different proportions of reagents gives a system of data which if graphed will form a surface which shows how the composition of the precipitate depends on the concentrations of the two reagents; two dimensional graphs can be made by showing appropriate sections of this.¹⁴

Most of the precipitating antisera that have been studied quantitatively thus far were obtained from the horse or the rabbit. In the horse there is a striking difference in the behavior of anti-protein antibodies and antibodies against bacterial polysaccharides; in the rabbit this difference is not found, but both kinds of antibodies resemble more the anti-carbohydrate antibody of the horse.

Sera from the two species differ in this way: in the horse it is found that if more than a certain relative amount of antibody is added no precipitate is produced, soluble compounds being formed (*i.e.*, horse anti-protein sera exhibit a prezone); whereas carbohydrates are precipitated even with large excess of horse antibody. Rabbit antibodies, whether against protein or carbohydrate, do not show a prezone with excess antibody. It may be suspected that the difference is at least partly due to a difference in solubility of the various antibodies,¹⁴ for it will be recalled that the anti-carbohydrate antibodies in the horse, and most antibodies of the rabbit, are predominantly found in the euglobulin (least soluble) fraction of the serum proteins, while the anti-protein antibody in the horse is mostly of pseudo-globulin (more soluble) character.

All precipitating systems exhibit the phenomenon of the postzone which is unfortunately usually called the prezone (since in precipitin reactions it is usually the antigen which is diluted); for this reason and for others, it seems best to use Heidelberger's term "inhibition zone" for the zone in which there is insufficient antibody to precipitate the antigen present. The antibody in this zone forms soluble compounds with the antigen.

The actual amount of precipitate obtained for a given amount of antiserum depends in the first place on the amount of precipitating antibody present, and second on the ratio of antibody to antigen in the precipitate, which in turn depends on the amount of antigen added. As increasing amounts of antigen are added, the amount of precipitate increases up to a maximum, then declines as the inhibition zone is reached. In the horse anti-protein systems a prezone with antibody excess is observed.

If the supernatants from such precipitates are tested for antibody and antigen, it is found that antibody is present in the first tubes (where insufficient antigen was added), and antigen present in the last tubes (where excess antigen was added). In the central part of the range one or more tubes will be found where there is either no antibody and no antigen, or small traces of both, in the supernatant. This is called the equivalence zone (Heidelberger). In some systems it is found that this zone

may coincide with, or lie near, the point of maximal precipitation. In other systems, however,^{56, 88} the point at which the maximal precipitate is obtained may lie in the region of antigen excess.

Influence of molecular weight of the antigen. Zinsser¹¹⁶ showed that the relative surface involved would explain the well known observation that less antibody is required to agglutinate bacteria than to precipitate, for example, a protein antigen. Boyd and Hooker^{16, 17} called attention to the fact that the ratio of antibody to antigen in precipitates made at the equivalence point (mid-point of equivalence zone) depends on the molecular weight of the antigen. The dependence is not absolute, as will be seen in Figure 2, which includes data up to 1940, but it was found that there was at least a highly significant degree of correlation between the two variables. Boyd and Hooker interpreted this tentatively as due to the fact that at the equivalence point the surface of the antigen molecule is just covered with molecules of antibody, which was supposed to act as a chain of three (or better, four) roughly spherical units of molecular weight about 35,000. It would do equally well to suppose that the antibody behaved as a long flexible ellipsoid. On the basis of such a picture it was possible to calculate by spherical geometry that the theoretical relation between molecular weight of the antigen and ratio by weight of antibody to antigen in the precipitates ought to be:

$$R = 37,800M^{-0.8} + 179M^{-0.85}$$

In Figure 2 this theoretical relation, shown by the solid line, is seen to fit the data rather well, considering the roughness of many of the measurements. It is doubtful, however, if we are justified in considering the polysaccharide molecules, here plotted at the value $M = 4,000$, as spherical, so it may be that part of the agreement is fortuitous. At any rate, it can be seen that the ratio does tend to diminish with increasing molecular weight of the antigen, falling from values of around 10 for antigens of molecular weight 35,000-40,000 to values of less than 1.00 for the large hemocyanin molecules of M W ca. 7,000,000.

How⁶⁸ has more recently derived an improved formula giving somewhat better agreement with the data.

When less than the equivalent amount of antibody is used, the precipitate contains less antibody, and we may suppose the surface to be only partly coated. When more antibody is used, the ratio of antibody to antigen in the precipitate goes up. If antibodies are really to be visualized as just described, it is necessary to suppose that some of the molecules in this case are not in full contact with the antigen surface, and when there is considerable excess of antibody we should have to visualize them as "standing on their heads."⁶⁴

Influence of proportion in which reagents are mixed. The composition of the precipitate depends on the final concentration of antibody or antigen in the supernatant, as would be expected if an equilibrium is reached.

But few direct measurements of such equilibrium concentrations have been made, however, because of analytical difficulties, whereas we can easily make precipitates by mixing antibody and antigen in various proportions. Therefore it is desirable to investigate also the way in which the composition of the precipitate depends on the ratio in which the reagents are mixed.

If to a constant amount of antibody there is added more than the equivalent amount of antigen, the compounds formed will have a lower antibody/antigen ratio. Above a certain point these compounds are soluble, in the case of all systems, and no precipitate is formed. We may refer to this region of no precipitation as the "zone of complete inhibition" or prezone. The ratio of antibody to antigen in the precipitate therefore never falls below a certain value which, if it could be measured, would give the approximate composition of the compound having the smallest proportion of antibody which will still precipitate. For small antigen molecules, this is

estimated at about two molecules of antibody to one of antigen, but for larger molecules as many as 30-40 molecules of antibody may be required to precipitate one molecule of antigen. This is shown in Table 5.

When the proportion of antigen remaining unprecipitated is small, serological methods,^{56, 61} can be used to estimate it, but the only analytical methods of general applicability to this problem depend on the use of antigens which are colored, or contain an inorganic atom which can be tested for chemically, or which contains some introduced prosthetic group which enables them to be detected.^{112, 113, 65, 55, 83} Only the last two groups of investigators made any extensive studies of the region of antigen excess. Malkiel and Boyd⁸³ found in their two systems that there was a linear relation between the ratio of antibody to antigen and the amount of antibody added to a given amount of antigen. Investigation showed that this relation probably held for other systems, for if the data of Heidelberger and Kendall⁵⁵ were plotted similarly, a straight line was also obtained.

In the region of antibody excess, Heidelberger and Kendall^{55, 56} have also reported another linear relation, between R and the amount of antigen, N , precipitated (from a constant amount of serum). Since in this region all (or nearly all) of the antigen is precipitated, this is in most cases equivalent to a linear relation between R and the amount of antigen added, thus: $R = a - b G_a$.

Farther in the region of antibody excess, where the antibody content of the precipitate approaches an upper limit asymptotically, a linear relation cannot be expected to hold, and it has been found that it does not. Heidelberger and Kendall^{55, 56} found that better agreement was obtained by plotting, not the linear equation referred to above, $R = a - b G_a$, (where R is the ratio of antibody to antigen in the precipitate, and G_a is the antigen added to a given quantity of antibody), but the curvilinear relation $R = a - b G_a^{1/2}$. The relation expected between R and G_a on the basis of the Freundlich equation gives for this region, when graphed, a line having a slight curvature, but nearly straight.

The equations used for the calculations of the predicted values of antibody precipitated were:

(1) $R = 1.325 - 0.714 G_a$ (Heidelberger and Kendall)

(2) $R = 1.58 - 0.968 G_a^{1/2}$ (Heidelberger and Kendall)

(3) $R = 14.84 p / (1 + 957 p)$ (Langmuir, Ghosh)

(4) $R = 1.57 p^{0.31}$ ("Freundlich")

In these equations R = the ratio by weight of antibody to antigen in the precipitate, G_a = antigen added, p = the concentration of unprecipitated antibody (mg in each 2 cc), shown in column 4 (obtained by subtracting the values in column 3 from 0.623), x = (true value of antigen precipitated - predicted value) $\times (10^2)$.

The expected values of "antibody precipitated" are calculated from the predicted values of R by multiplying by the amount of antigen precipitated.

In Table 4 will be found data on the composition of precipitates in the region of antibody excess and an example of the fitting of experimental data by the two equations of Heidelberger and Kendall and by simple equations of the "adsorption" type. All predict the composition of the precipitate moderately well. The least squares technic indicates that in the present case definitely the best fit is obtained with the "Freundlich" type of equation.

The suitability of the others decreases in the order: Heidelberger and Kendall's empirical equation, their theoretical equation, the Langmuir-Ghosh equation. The fit obtained with the Freundlich equation is about as good as could be expected from the data. Other sets of data might conform better in some cases to one or the other equations.

Molecular composition of the precipitates. The application of quantitative methods to the study of the precipitin reaction, plus the recent determinations of molecular weights of various proteins, including antibodies, by the ultracentrifugal technic, have enabled the calculation of the actual molecular composition of precipitates made under various conditions. In Table 5 are given the results of the studies of Heidelberger and collaborators⁵² to which have been added results calculated from the data of Malkiel and Boyd,⁵³ Pappenheimer,⁹¹ Heidelberger, Treffers and Mayer,⁶⁰ and Pappenheimer, Lundgren and Williams.⁹²

Table 5. Molecular Composition of Specific Precipitates

| Antigen | Antibody | Empirical composition of precipitate at | | | | Composition of soluble compounds in zone of partial inhibition |
|----------------------|----------|---|---|--|-------------------------------|--|
| | | extreme antibody excess | antibody excess end of equivalence zone | antigen excess end of equivalence zone | zone of partial inhibition | |
| pvalbumin | rabbit | A ₅ G | A ₃ G | A ₅ G ₂ | A ₂ G | (AG) |
| dye-ovalbumin | rabbit | (A ₅ G) | (A ₃ G) | A ₅ G ₂ | A ₃ G ₄ | (AG ₂) |
| serum albumin | rabbit | A ₆ G | A ₄ G | A ₃ G | A ₂ G | (AG) |
| thyro-globulin | rabbit | A ₄₀ G | A ₁₄ G | A ₁₀ G | A ₂ G | (AG) |
| viviparus hemocyanin | rabbit | | A ₁₂₀ G | A ₃₈ G | A ₃₆ G | |
| diphtheria antitoxin | horse | A ₃ G | A ₄ G | A ₃ G ₂ | AG | AG ₂ |
| ovalbumin | horse | (A ₄ G) | A ₂ G | | AG | (AG ₂) |

A = antibody, G = antigen

Formulas in parentheses are somewhat uncertain.

From Table 5 it may be concluded, since the ratio of antibody to antigen in precipitates is observed to vary continuously, that if the above formulas really represent the composition of the various antibody-antigen possible, the precipitate obtained at any particular point is a mixture of two or more of these compounds.

Allergy and Anaphylaxis

CARL A. DRAGSTEDT

Professor, Northwestern University Medical School, Chicago, Ill.

The terms *allergy* and *anaphylaxis* are used to include a considerable variety of biological reactions in which some foreign substance (antigen, allergen, anaphylactogen) provokes a reaction not by virtue of its inherent or specific pharmacological characteristics, but rather by virtue of some changed reactivity, hypersensitiveness, or hypersusceptibility of the animal or organ to which it is administered. Such reactions include the "true anaphylaxis" induced in experimental animals, as well as serum reactions, pollen, food and drug idiosyncrasies occurring in man. Richet introduced the term *anaphylaxis* to signify the antithesis of prophylaxis, with special reference to the hypersusceptible condition induced in experimental animals by a suitable preceding inoculation with various toxins. Von Pirquet introduced the term *allergy*, meaning altered reactivity, with special reference to the reactions of serum sickness in man and which he felt were analogous to those of the experimental animal. The experimental condition lent itself readily to analysis; and it soon became evident that any substance, whether toxic or not, which can induce antibody formation by injection into an animal (and therefore called an antigen), can initiate the change in the animal called sensitization, and, when reinjected after an appropriate interval or incubation period, can provoke a chain of symptoms of a highly characteristic nature, referred to as anaphylactic shock.

A convincing demonstration that this acquired sensitive state is dependent upon antibody formation was made by conveying a similar sort of sensitivity to a normal animal by injecting the blood serum of either a "sensitive" or an "immune" animal into a normal animal. Such a procedure, which is called passive sensitization, seems absolute proof of the association of sensitization with some sort of humoral antibody, since the recipient animal becomes sensitive after a latent period of a few hours, which seems too short a time for it to have generated its own reactivity. Laboratory methods can demonstrate the presence in the blood from sensitized animals of precipitins in a concentration which appears correlated with the degree of sensitivity of the animal and with the potency of the blood in conveying passive sensitization. Inasmuch as the apparently spontaneous conditions occurring in man were not so readily proved to be associated with an antigen-antibody reaction, but had nevertheless a certain similarity in basic pattern, Doerr extended the meaning of the term *allergy* to include all forms of changed reaction capacity, whether the substance which provoked the altered reaction was demonstrable as an antigen or not. Thus in Doerr's nomenclature, anaphylaxis is one form of allergy.

Cocoa advocated *hypersensitiveness* as a general designation, classifying this as anaphylaxis where the reactions clearly depended upon an antigen-antibody reaction,

and as allergy those reactions in which no such relationship exists. There are two objections to this use of terms. In the first place it seems to pass final judgment that the allergic reactions are not antigen-antibody reactions, while the facts seem to indicate that it is only rather difficult to demonstrate specific antibodies in this case. In the second place, the term *hypersensitiveness* seems more appropriately descriptive of a quantitative rather than qualitative change in sensitivity. For example, we can artificially induce an enhanced sensitivity to epinephrine in an animal by the prior administration of cocaine, but the character of the reaction remains unchanged and is characteristic of epinephrine. Such examples of bona fide hypersensitiveness are not common, but they do exist, and they are different both in pattern and pathogenesis from allergic or anaphylactic reactions, in which the character of the response is not characteristic of the provocative agent.

The space allotted to this resume does not permit a comprehensive discussion of these phenomena, but a digest of the important characteristics of true anaphylaxis provides a good foundation for the consideration of all related reactions. Almost any protein, when injected parenterally, even in a dose which has no observable effect, can render almost any animal sensitive, so that the reinjection of this protein, after a suitable interval, will provoke an anaphylactic response. This general statement requires considerable qualification. All proteins are not equally effective (*i.e.*, equally antigenic or anaphylactogenic). Gelatin, hemoglobin, etc., are relatively ineffective. There is some evidence to indicate that the character of the amino acid content of a protein may determine its antigenic properties, but there is also the possibility that molecular size, etc., may be determining factors. All animals are not equally susceptible to sensitization. Guinea pigs are perhaps the most readily sensitized. Dogs, rabbits, monkeys, and rats are respectively less so. Other species demonstrate varying degrees of susceptibility. Such evidence as is available from inadvertent experiences in medical practice seems to indicate that most people are not readily sensitized. While some explanations for the species variations can be offered, no ultimately determining factors have been established. Within a given species there may be wide variations in susceptibility to sensitization. Whether this is due to genetically determined constitutional differences, to environmental factors, or both, is not fully known. There is considerable evidence to indicate a hereditary predisposition to allergic disease in man, and it may be that there is a corresponding hereditary factor in the experimental animal.

A suitable interval (incubation period) must elapse between the sensitizing and the assaulting injection for maximal reactions to occur. Seven days is an approximately minimum time, the optimal times varying in different animals up to three or four weeks. The sensitive state may persist in some animals (*e.g.*, guinea pigs) for many months or decline fairly rapidly in others (*e.g.*, rabbits). The assaulting injection is most effective in producing shock if made intravenously; a certain adequate dose is necessary, but further than this there is no absolute correlation between the size of the dose and the degree of the shock reaction produced. We may properly infer from this and the preceding characteristics that the antigen is not toxic *per se* but acts by some trigger mechanism to initiate a reaction whose severity rests upon a more complicated basis. As mentioned, the reaction may vary in severity from one of almost negligible symptoms to that of a violent and rapidly fatal form. For a certain period after recovery from a non-fatal reaction, the animal fails to react if the antigen is readministered. This abrupt loss of reaction capacity is called desensitization. This desensitization lasts only a few days in most cases, and the preceding sensitive state recurs. Experiments have shown that certain isolated smooth-muscle organs (such as uterus, intestine, etc.), when washed as free as possible from the blood of the sensitive animal from which they have been obtained, will react (by contraction) when exposed to the antigen to which the animal was sensitized. For this (and other reasons) the conception prevails that in an

intact animal an anaphylactic reaction occurs as a result of the interaction between the antigen and antibodies which are somehow bound to the fixed tissue cells. Since such isolated tissue preparations also show the phenomenon of desensitization, and since the blood of an animal which has been desensitized may not lose its ability to convey passive sensitization, it is generally assumed that desensitization is related to a temporary binding of fixed or sessile antibodies with antigen in some loose manner.

A comprehensive consideration of anaphylaxis, therefore, involves a variety of problems. For example, what are the ultimate factors which determine whether a given substance can function as an antigen, or more precisely as an anaphylactogen? What are the factors which determine the sensitizability of a given animal? If this is directly related to the animal's antibody production capacity, then what are the antibodies concerned, what is their origin and fate, and what conditions promote or inhibit their production? What is the physiological reaction which takes place when the antigen is injected, or, in other words, how can all the phenomena of anaphylaxis be accounted for? What is the explanation for the occurrence and the loss of the desensitization which follows a reaction? And finally, what appears to be Nature's purpose or design that such a reaction should occur? Is it some sort of defense reaction which has greatly overextended itself, or one which has taken an anomalous turn? Since it is not possible to answer all these questions, attention will be devoted primarily to the question of the proximal pathogenesis of the symptoms and phenomena of the anaphylactic reaction.

That all anaphylactic reactions in all animals have a similar fundamental mechanism is indicated by two general considerations. First, the basic pattern as to sensitization, incubation period, desensitization, etc., is strikingly similar in all cases. Secondly, the same foreign protein may serve as the anaphylactogen in several species of animals on the one hand, while on the other the character of the anaphylactic reaction in any given species of animal is always the same, even though widely different anaphylactogens are used. This is true even when the latter has its own inherent toxic properties, in which case the end effect is a composite of the anaphylactic and specifically toxic reactions. Since, however, the symptomatology of anaphylaxis is different in the various species of animals in which it has been studied, the necessity arises of scrutinizing and harmonizing this apparent discrepancy.

First known and often referred to as the Theobald Smith phenomenon, the anaphylactic reaction in the guinea pig was extensively studied by Otto, Rosénau and Anderson, and many subsequent investigators. After the intravenous injection of antigen into a sensitized animal, there is a prodromal period of $\frac{1}{2}$ to 3 minutes during which the animal usually sneezes, scratches its nose, becomes restless, discharges urine and feces, becomes weaker and lies down; acute respiratory difficulty then develops, and death from asphyxia may follow in 2 to 10 minutes. Intraperitoneal or subcutaneous injection of the antigen is much less certain, but may produce death with similar symptoms. The first analysis of the physiological mechanism involved was that of Auer and Lewis. They demonstrated that the respiratory difficulty and asphyxia were due to a swiftly developing stenosis of the bronchioles, and that in spite of violent respiratory efforts the animal was unable to effect any air exchange. They demonstrated that this bronchial reaction occurred in animals which had been curarized, whose vagi had been cut, or whose spinal cord, medulla and basal brain had been destroyed, indicating that the reaction occurred peripherally. The observations of Auer and Lewis have been confirmed by numerous workers and the demonstration by Dale that the bronchospasm can be reproduced with the isolated, perfused lungs corroborated their conclusion that it was due to a direct action on the muscular walls of the bronchi and not due to a central or reflex nervous reaction. Auer and Lewis, Anderson and Schultz, and Loewit have recorded the systemic blood pressure in anaphylactic guinea pigs and report that there is an initial moderate rise followed by a gradual fall, such as occurs in asphyxia from any cause. It is

thus generally accepted that the predominant reaction is pulmonary and that the circulatory effects are secondary in importance.

Less prominent in the symptomatology are a pronounced fall in body temperature and a slight to moderate deficiency in the coagulability of the blood, which may be preceded by a brief period of noticeable hypercoagulability, a temporary leucopenia, etc. The most prominent post-mortem finding is the characteristic emphysematous distension of the lungs, while less noticeable are passive congestion of the liver and petechial hemorrhage in the intestines.

The first experimental study of anaphylaxis in the rabbit was made by Arthus. In this animal the reaction reveals itself either as a local or a general manifestation, depending upon the method of administration of the antigen. When the shocking injection is made subcutaneously (or intracutaneously, etc.), there may result infiltration, edema, sterile abscess or gangrenous slough at the site of the injection. This local reaction was first described by Arthus and is generally referred to as the Arthus phenomenon. When the reinjection of antigen is made intravenously the general reaction is seen. The respiration quickens, the animal sinks upon its abdomen, feces and urine are usually expelled, a fleeting hyperemia followed by pallor of the ears may be seen, and the animal may die in a few minutes. The respiration does not become dyspneic as it does in the guinea pig, and although some bronchospasm occurs it is seldom marked enough to cause asphyxia. The carotid blood pressure falls greatly, this fall sometimes being preceded by a temporary rise. There is an accompanying marked rise in the pulmonary artery pressure, and a number of workers have shown that the circulatory failure is mainly due to a pronounced obstruction to the flow of blood through the pulmonary circuit. Gilbert has shown that a marked contraction of the pulmonary arterioles occurs which may partly account for this, while an additional factor is probably the aggregation of leukocytes into emboli which obstruct the smaller pulmonary vessels, a phenomenon witnessed by Abell and Schenk in the ear vessels. There may be a minor cardiac element to the circulatory failure, as Rocha e Silva has shown that occasionally section of the vagi during the fall of the systemic blood pressure may produce a prompt recovery. This vagal inhibition of the heart seems to be a reflex secondary to the pulmonary phenomena and is probably comparable to that which is often seen associated with pulmonary embolism. Diminished coagulability of the blood, leucopenia, and fall in body temperature are usually found.

The analysis of the anaphylactic reaction in dogs began with the work of Richet, was soon amplified by Biedl and Kraus, Arthus, and many subsequent workers. In the unanesthetized animal the prominent symptoms are salivation, vomiting, diarrhea, dyspnea, and profound weakness. There is a marked fall in the systemic blood pressure. This is not due to cardiac weakness, but is readily shown to be due to peripheral vascular reactions. There is a marked swelling and engorgement of the liver, associated with a marked rise in the portal vein pressure, indicating a marked impairment to the flow of blood through the liver. Weil ascribed this obstruction to the swelling of the hepatic parenchymal cells; and Simonds has presented evidence that it may be accounted for by a contraction of the smooth muscle in the hepatic veins, which is particularly abundant in this animal. A number of workers have shown that anaphylactic shock is prevented entirely or greatly reduced in severity if the liver is either removed or short-circuited out of the circulation. The hepatic reaction, therefore, plays a dominant role in the genesis of the symptoms in the dog. In this animal, defective coagulability of the blood is a prominent finding, occurring in a large percentage of shocked animals, and not infrequently achieving a state of complete incoagulability.

Although there is thus a difference in the gross pictures of anaphylaxis as expressed in the guinea pig, rabbit and dog, there is a striking uniformity in the underlying physiological reactions. A contraction of smooth muscle, a dilatation of

capillaries, an increased secretion of various glands, a deficiency in the coagulability of the blood, a temporary leucopenia, and a drop in body temperature are common to all species. Simonds was one of the first to point out that contraction of strategically located smooth muscle (*i.e.*, in the bronchi of guinea pigs, in the pulmonary arterioles of rabbits, in the hepatic veins of dogs) could explain the divergence in symptomatology which is met with in different animals on the basis of an identical physiological reaction. Since the phenomena which can be interpreted as consequences of such smooth-muscle contraction include the most prominent elements in the category of symptoms (*e.g.*, bronchospasm in guinea pigs, circulatory failure in rabbits and dogs) there was for a time a tendency to view smooth-muscle contraction as the essential anaphylactic response, and to consider all the other phenomena as subjacent thereto. For many years, therefore, the conviction prevailed that if there were an anaphylactic poison (anaphylatoxin) into which the antigen was metamorphosed upon its injection, or which developed from any other source, that it must possess smooth muscle stimulating properties.

During the past ten years evidence has accumulated which permits the statement that histamine has been proved to be the smooth-muscle stimulating factor which is probably largely responsible for many of the symptoms of anaphylactic shock. The evidence seems unequivocal for the dog and the guinea pig, and virtually so for the rabbit. The evidence indicates that the histamine does not originate from the injected antigen, but is liberated from the tissues of the sensitized animal. In the dog the liver appears to be the major source, in the guinea pig the lungs, and in the rabbit the cellular elements of the blood. With the recognition that an agent mediating at least some of the symptoms of anaphylaxis could be isolated and identified in the blood and lymph as an initial consequence of the anaphylactic response, efforts to detect other such agents were intensified. Heparin has been isolated from the blood of anaphylactic dogs, shown to be adequate to account for such defective coagulability as occurs, and shown to be derived almost exclusively from the liver. That heparin is responsible for the defective coagulability of the blood in rabbits and guinea pigs is highly probable. Kellaway and Trethewie have presented evidence for the liberation of an unidentified principle which they call Slow Reacting Substance (S-R-S), during *in vitro* anaphylaxis in guinea pigs. There is a certain amount of suggestive but unconvincing evidence that choline or acetylcholine and potassium may be liberated from tissue sources and mediate some of the symptoms. If the role which such agents play is similar to, but relatively inconspicuous in comparison with that of histamine, etc., it is obvious that it is difficult to clearly establish or definitely deny their causal significance.

The cardinal symptoms of anaphylaxis can thus be explained as being due, in the immediate instance, to an autointoxication produced by physiologically active substances liberated from the tissues of the sensitized animal. If we attempt an inventory of all of the anaphylactic phenomena, in a much more detailed fashion than that presented previously, we find that there are a number of reactions which are not accounted for by the major anaphylatoxins, histamine and heparin, nor by the minor anaphylatoxins, choline, acetylcholine, S-R-S, or potassium. Some of these are the transitory hypercoagulability of the blood, which precedes the hypocoagulability, the decreased sedimentation rate of the erythrocytes, etc. Though histamine can account for the fatal bronchospasm in the guinea pig, the violent circulatory effects in rabbits and dogs, and heparin for the characteristic incoagulability of the blood during anaphylaxis, neither of these agents, alone or combined, can completely account for the local necrosis, etc., of the local anaphylaxis, or Arthus reaction. That the latter is a counterpart of the general anaphylactic reaction, dependent upon an antigen-antibody reaction, etc., is clearly established. Careful morphologic studies of the processes underlying the Arthus reaction demonstrate such a marked similarity to those of an acute inflammatory reaction, that one seems warranted to state

that an anaphylactic reaction is merely an exaggerated inflammatory reaction. The imprint of histamine in the capillary dilatation, permeability and local edema is clearly evident, but histamine alone cannot account for either the leukocytic response or the necrosis of tissue. It is thus clear that, though we can explain most of the phenomena of anaphylaxis, we cannot at present explain them all. There are some hints from both early and late investigations which suggest that some of the unexplained phenomena may be related to enzyme reactions, but the present status of this evidence does not warrant discussion here.

As yet little can be said regarding the manner in which the injected antigen provokes the liberation from the tissues of these varied cellular reactants. From studies on reactions which closely simulate anaphylaxis in symptomatology (peptone shock, venom reactions, etc.), it is known that these same anaphylatoxins can be liberated without any known antigen-antibody reaction being concerned. Feldberg, viewing the composition of cell boundaries as that of a mixed lipoprotein film, has pointed out how either a protease or lysolecithin could act as the intermediary histamine-releasing factor. That either or both are concerned seems highly probable, but how they in turn are provided the opportunity to act is not known.

As to the allergic reactions of man, our information is not so extensive or so definitive. Since reactions which are virtually identical with anaphylaxis, both in symptoms and pathogenesis, can be induced in the experimental animal without the participation of an antigen-antibody reaction, the inability to incriminate an antigen-antibody reaction in human allergies does not necessarily set them apart as fundamentally different reactions. It has been shown, however, in a great many cases of varied types of allergy that some sort of humoral agent was present in the blood of the allergic patient which by suitable injection could convey a temporary passive sensitization to the skin of a normal individual. For various reasons of apparent dissimilarity to the precipitins of anaphylactic animals, these humoral agents have been called reagins. Recently, however, using improved methods, Cannon has been able to show precipitins in the blood of patients who were allergic to various substances. It seems highly probable that many reports indicating the absence of antibodies in the human case represent failures to find them rather than conclusively negative evidence. That the symptoms of allergic reactions, which display such manifold patterns as those of hay fever, asthma, angioneurotic edema, etc., are in turn produced by cellular by-products such as histamine, heparin, etc., can neither be categorically affirmed nor denied. It can be stated that these diverse reactions could largely be accounted for by these agents and that there is a considerable amount of circumstantial evidence to substantiate this. There is in addition a certain amount of direct evidence that merits mention. Randolph and Rackemann have observed a significant increase in the blood histamine of patients during paroxysms of asthma. Katz has shown that the application of the specific allergen to the skin of ragweed-sensitive patients leads to a liberation of histamine which parallels the severity of the local reaction. That the demonstration of a relationship between the various symptoms and the agents which may mediate them is not so simple in the human case is readily understandable. In the first place, in the animal experiment we can deal with a reaction which is of explosive violence and perhaps fatal in its termination. In the second place, it must be considered that many, if not most, of the allergic reactions of man are confined to restricted tissues in which the reaction may occur and direct access to the detection of mediating agents is difficult and inconclusive. In summary, it seems warranted to accept Zinsser's view that "all forms of hypersensitiveness represent essentially one and the same basic phenomenon when analyzed with understanding of superficial variables" and to deny that man "possesses a sort of immaculately conceived hypersensitiveness that, like his soul, distinguishes him from the animal kingdom."

Homeostasis: The Maintenance of Steady States in the Organism

WALTER B. CANNON

Professor, Harvard Medical School

The extreme instability of parts of the body structure in the higher vertebrate, their readiness for disturbance when only slight external forces are applied, and their rapid deterioration in the absence of favorable conditions, render the persistence of a normal state and of normal activity through many decades an extraordinarily remarkable phenomenon.* Its extraordinary character is emphasized by the fact that the organism is an open system engaging in free exchange of material with the outer world, and by the further fact that bodily structure itself is not permanent but is being continuously broken down by activity and continuously restored by the process of repair.

The ability of organisms to maintain a fairly constant state has long impressed biologists. The ancient phrase "*vis medicatrix naturae*" recognized factors which repair the normal state when that has been damaged. An important contribution toward understanding the phenomenon of organic stability was offered by Claude Bernard about ninety years ago. He pointed out that metazoa have two environments: an external environment as have other objects, and also an internal environment. This internal environment is made of the fluids which bathe the living parts of the body: tissue fluids, lymph, and especially blood. Bernard called this the *milieu interne*. It may be regarded as the "fluid matrix" of the organism (cf. Cannon, 1929, 1939a). In so far as the fluid matrix is kept constant, organisms are independent of limiting changes which might be imposed by the external surroundings or by the disturbances produced by bodily activity. The freedom thus assured is a privilege of the higher vertebrates, birds and mammals. It is a freedom which has been gradually evolved. For example, the frog, in which control of body water and temperature is lacking, is restricted in the summer to the vicinity of a moist region,

* The relatively slow changes due to ageing are considered in a paper by A. J. Carlson in this volume. J. A.

and in the winter must sink to the bottom of a frigid pool. Only when spring returns is he freed from the paralyzing effects of icy water. Birds, on the contrary, with their feathery covering, may spend the cold winter months in vigorous activity because of special devices for keeping warm.

The constancy of the fluid matrix is controlled by the organism itself. In that control many complex physiological processes may be involved. The term "equilibrium," which is technically applied to simple physical and chemical systems, does not imply the complicated arrangements in the body for preserving uniformity. Consequently, the relatively stable state maintained in the fluid matrix has been given the special name "homeostasis" (Cannon, 1929).

Essential Role of the Fluid Matrix

When there is danger that the blood may be lost from the body by injury to blood vessels, the blood coagulates at the point of injury. A clot is attached to the edges of the broken surface and thus, sealing the opening, it stops the blood loss. By physiological reactions within the organism, excessive bleeding is accompanied by an increased speed of the clotting process. In an experimental hemorrhage, loss of 13 per cent of the estimated blood volume reduced the clotting time from 7 to 3 minutes. Removal of 10 per cent more reduced the time from 3 minutes to 1 minute (Gray and Lunt, 1914). For later interest it may be stated that more rapid coagulation of blood can be induced by injection of adrenalin and that a large hemorrhage is associated with extra activity of the sympathetic nervous control of the adrenal medulla and consequent discharge of adrenalin into the blood stream.

When muscles become active many capillaries, closed during muscular rest, are opened to such a degree that they may appear to be from 40 to 100 times as numerous in the contracting as in the relaxed muscle; the blood flow may be 5 times as great through the active muscle as through the inactive, thereby supplying extra oxygen and energy-yielding material for the vigorous processes which are taking place. Also the greater volume flow of blood carries away extra waste resulting from these processes. In time of need, therefore, adjustments provide for local homeostasis, *i.e.*, for local preservation of uniform conditions (Cannon, 1936b).

Furthermore, there are special provisions for maintenance of steady states in essential and peculiarly sensitive structures, notably the delicate neurons of the cerebral cortex and the muscle of the continuously active heart. Unless a sufficiently high arterial pressure is present, the delivery of oxygen to these organs will be inadequate. If there is a loss of 15 to 20 per cent of the estimated blood volume, a sharp fall of blood pressure ensues. Only a few minutes elapse, however, before the pressure is restored to approximately the former height, thus assuring a proper blood supply to the brain and to the heart. The restored blood pressure results from reflexes from the vascular system itself, which so operate that the blood vessels generally throughout the body, except in the heart and the brain, are contracted to a degree which fits the capacity of the vascular system to the reduced volume of blood and thereby maintains in these essential organs an adequate oxygen delivery. There is in this preferential treatment a lessened delivery to other organs in which the blood vessels are constricted. These organs, however, are more hardy and can endure the condition for a relatively long period (Cannon, 1923).

Associated with a loss of the fluid matrix by hemorrhage is another compensatory device, the contraction of the spleen, an organ in which corpuscles are stored in concentration. By splenic contraction, the stored corpuscles are discharged into the blood stream and become useful at once as oxygen carriers (Barcroft, 1925).

TYPES OF HOMEOSTATIC REGULATION

Two general types of homeostatic regulation can be distinguished, dependent upon whether the steady state involves supplies or processes.

Homeostasis by the Regulation of Supplies

Homeostasis of supplies is provided for by *storage*, as a means of adjustment between occasional abundance and later privation and need, and also by *overflow* or discharge from the body when there is excess. Two types of storage can be distinguished: a temporary flooding of the interstices of loose tissue by material in solution, *i.e.*, storage by inundation; and an inclusion of material in cells or in other relatively fixed structures, storage by segregation.

Storage by Inundation. Somewhat as a stream passes through a bog or swamp, the circulating blood in the capillaries sweeps by the more stagnant extravascular fluids. Just as in time of flood swamp water rises, so in time of abundance there is an outflow from the capillaries into the loose connective tissue under the skin and around and between muscles and muscle bundles. In this meshwork and bound by it in some manner, water and dissolved substances appear to be held.

Water. Water storage in the extravascular regions passes out from them as it is needed, *e.g.*, a dog deprived of water for three days showed no change in the freezing point of the blood (Mayer, 1900). Clearly, constancy was preserved in spite of continuous loss of water through the lungs and the kidneys, a constancy due to seepage into the blood from the inundated reservoirs. Evidence indicates that most of the water which leaves the reservoirs, *e.g.*, after a hemorrhage, comes mainly from the muscles and the skin (Skelton, 1927).

Probably storage by inundation, and release from storage, are managed through a balance between filtration pressure through the capillary walls and osmotic pressure of the proteins of the blood plasma, working in opposition. Doubtless there are other factors. With the taking of sodium chloride, there is a markedly increased retention of water in the body. Probably other electrolytes play a role. That the thyroid gland is influential is indicated by the great increase of protein in the plasma and of albumin in the tissues in conditions of low thyroid activity, and the disappearance of these conditions, together with a large release of water and sodium chloride when thyroxine is administered. How these various factors coöperate when water and sodium chloride are needed in the circulation, as after hemorrhage, is not clear.

The importance of retention of water in the body to preserve homeostasis is indicated by physiological provision for saving it when there is dearth. It is known, for example, that an extract of the posterior lobe of the pituitary gland will check the water loss through the kidneys. If the water load in the body is reduced, the amount of such an extract administered intravenously may be considerably less as a check on urine production than if the water load is abundant. It would appear, therefore, that a large water load inhibits the release of the anti-diuretic substance from the pituitary gland; consequently, the amount of extract required to check the flow of urine is greater than when the load is small. With a small load the requirement of the extract would be less because a protective anti-diuretic substance is secreted from the pituitary source (*cf.* Pickford, 1936).

Sodium Chloride. Concentration of sodium chloride in the blood plasma and lymph is remarkably steady. Among the electrolytes it is the main agency for maintenance of a uniform osmotic pressure in the circulating fluids. It is stored in times of excess, as shown by its retention in the body. If concentrated sodium chloride is taken by mouth, only a small part of the amount ingested may appear in the urine; most of it may be stored in the body; and even thereafter if enough water is drunk to produce a diuresis the urine has a low salt content, *i.e.*, the salt is not readily released from its storage place. With a fairly constant chloride intake, a loss of chloride through the skin by sweating is accompanied by a great reduction of chloride output in the urine—a condition which continues, although thereafter a diet rich in salt is taken; in such circumstances a compensatory retention of as much as 14 grams of sodium chloride has been observed.

When a search is made for the location of the sodium chloride reserve, the highest percentage is found in the skin; indeed, on a chloride-rich diet 33 per cent of the chloride of the body may be in the skin. If animals are fed on a chloride-poor diet, between $\frac{1}{3}$ and $\frac{2}{3}$ of the chloride content of the body is lost, and of this amount between 60 and 90 per cent comes from the skin (the skin constitutes only about 16 per cent of the total body weight (Padtberg, 1910)). Whether sodium chloride is held in the skin by adsorption on surfaces in areolar tissue or by solution in interstitial fluid of the areolar spaces has not yet been definitely determined. Probably it is osmotically inactive. The evidence appears to be clear, however, that sodium chloride and water are closely related in their storage in the organism.

Glucose. Like excessive sodium chloride, excessive blood sugar finds its first temporary depository in the skin. If sugar or other readily digested carbohydrate is taken in abundance, the concentration of glucose in the blood commonly rises from about 100 to 170 mg per cent. After the digestive process has subsided the glycemic percentage likewise subsides. During the period of high concentration of glucose in the blood there is also a high concentration in the skin (Folin, Trimble and Newman, 1927). The drop in the glycemic level occurs as the circulating glucose is utilized or placed in more permanent storage in the liver and in muscle cells. At the same time with the drop in the glycemic level, the more concentrated glucose which has overflowed into the subcutaneous net of areolar tissue and possibly into other regions where this tissue is abundant, gradually seeps back into the blood again and then follows the usual courses of blood glucose into use or into fixed reserves.

Storage by Segregation. This mode of storage, commonly within cells, is stable and lasting. It differs from storage by inundation in being subject to more complicated control and in involving, as a rule, changes of physical state or of molecular configuration. In some instances it is known to be subject to nervous or neuro-endocrine government. There are, however, large gaps in the knowledge of ways in which substances are segregated in times of abundance and released from segregation in times of bodily need.

Carbohydrate. The best example of homeostasis by means of segregation is offered by arrangements for storage and release of carbohydrate. Plentiful intake of carbohydrate food results in large reserves of glycogen in the liver; prolonged muscular work draws upon these reserves until they may be largely depleted; and yet the rate of release is so nicely regulated that the blood sugar is maintained at a degree of concentration which results neither in sugar loss through the kidneys nor in disturbances due to hypoglycemia.

The control of the glucose concentration of the blood is complex. Various glands of internal secretion are involved: the anterior lobe of the pituitary, the thyroid, the adrenal cortex, the adrenal medulla and the islet cells of the pancreas. It appears that the endocrine agencies most directly concerned with maintenance of the normal glycemic level are the pancreatic islets and the adrenal medulla.

When insulin is injected in sufficient proportions, it lowers the glycemic concentration of the blood. As the concentration falls to about two-thirds of the usual degree, a "hypoglycemic reaction" occurs, characterized by pallor, rapid pulse, dilated pupils and profuse sweating—all signs of sympathetic activity. This hypoglycemic state calls into action the nervous organization which discharges adrenaline from the adrenal medulla into the blood stream. Adrenaline, by acting on the liver cells, mobilizes the glycogen stored within them and thus increases the sugar in the blood. It is clear that reduction of the glycemic percentage below a critical level calls forth an agency which acts to correct the condition (Cannon, McIver and Bliss, 1924).

If the sympathico-adrenal system is ineffective in checking the fall of blood sugar, convulsions are likely to occur when the concentration is reduced to about

half the normal concentration. Each convulsion is associated with a maximal display of sympathico-adrenal activity. If the liver is well supplied with glycogen, such extreme activity can restore the blood sugar to the normal level and thus abolish the condition which occasioned the convulsive attacks. That it is secreted adrenaline which protects the organism against coma and death (if the glucose concentration falls to a very low level), has been shown by evidence that adrenaline and not nervous control of the liver cells is the effective factor (see Cannon, 1940).

Agencies opposed to the sympathico-adrenal operations are those which operate with excess of glucose is ingested. The blood sugar then rises to a level close to that at which it escapes through the kidneys, but ordinarily it does not surpass that level. The excess sugar, apart from that set aside by inundation, is either stored in the liver or in the muscles, is converted into fat, or is promptly utilized. Evidence indicates that this process of storage is dependent on the insulin secreted by the pancreatic islets. The items of this evidence are as follows: (1) If the islet cells are removed hyperglycemia promptly occurs, and with it a great reduction of the hepatic glycogen reserves; (2) the administration of insulin to sugar-fed depancreatized dogs reduces the glycemic concentration to the normal range and causes glycogen to accumulate again in the liver; (3) in the absence of the liver, injected insulin augments the glycogen deposit in muscles, especially when extra glucose is provided; (4) when only a remnant of the pancreas is present and carbohydrate is fed, the islet cells degenerate and show signs of overwork; it would appear, therefore, that hyperglycemia stimulates the cells to secrete.

Although the internal secretion of the pancreas can operate effectively when wholly separated from the nervous system, there is testimony that the vagus nerves can in certain special circumstances cause an augmented discharge of insulin. Much as the sympathico-adrenal system serves to bring forth sugar from the liver rapidly in emergencies, so does the vago-insular apparatus seem to serve for storing reserves when there is excess glucose in the blood. Neither the sympathetic nerves nor the vagi are required, however, to maintain the usual glycemic concentration, for in the absence of these nerves that concentration is preserved. By determining simultaneously the rate of blood flow through the liver and the glucose content of the inflowing and outflowing blood, it has been shown that during control periods the liver secretes glucose into the blood stream, but that when glucose is abundantly supplied secretion ceases and the sugar is retained (Soskin, Essex, Herrick and Mann, 1938). It is very possible that reversible enzyme action provides for routine adjustment between plenty and dearth, and nervous control serves for conditioning or emergencies.

The manner in which the anterior lobe of the pituitary gland is involved in the homeostasis of blood sugar is not well demonstrated. If a diabetic hyperglycemia has been produced by removal of the pancreas, a subsequent removal of the pituitary lobe reduces the hyperglycemia (Houssay and Biasotti, 1931). Similar lowering of the glucose concentration of the blood occurs after removal of the adrenal cortex. Injection of an extract of the anterior lobe of the pituitary produces hyperglycemia, and if continued can cause diabetes. In this complex of endocrine influences the role played by each factor is still obscure. The possibility of disorder due to a variety of agencies which can affect the glycemic concentration, renders limitation of the range of that concentration in normal conditions all the more admirable.

Protein. The constancy of body structure is perhaps the most widely manifested evidence of the homeostasis of protein. That constancy includes also the blood, and since the steady states of the blood are of prime concern particular attention is now paid to that phase of the subject. Because plasma proteins exert osmotic pressure and ordinarily do not escape through capillary walls, they prevent the salt solution of the plasma from passing freely into perivascular spaces or escaping from the

body through the renal glomeruli. When, after an experimental hemorrhage, the corpuscles are returned to the body suspended in salt solution (the process of plasmapheresis), the immediate effect is a reduction of plasma proteins from about 6 to 2 per cent. Within fifteen minutes, however, there is a prompt rise in the concentration, followed by a gradual restoration thereafter until at the end of 24 hours there has been a 40 per cent recovery. Full recovery occurs in 2 to 7 days. Possibly the prompt rise is relative, due to an escape of salt solution from the blood vessels into perivascular spaces or through the kidneys. The slower recovery seems certainly to be dependent on the liver, for if the liver has been poisoned, restoration of the plasma protein is delayed; or if the return of blood from the intestines is shunted directly into the vena cava, thus sidetracking the liver, there may be no restoration for the first three days; or if the liver is unable to act, fibrinogen, which is usually completely restored within twenty-four hours, is not thus restored (cf. Whipple, 1938).

That the liver is important for homeostasis of plasma proteins raises the question whether protein is stored in that organ. Histological studies have shown that when animals are fed abundant protein food there appear in the hepatic cells fine droplets or masses reacting as protein material does, disappearing during a fast and reappearing when proteins or amino acids are fed. This histological observation is confirmed by biochemical analyses, which have shown that in well-fed animals the total nitrogen of the liver in relation to that of the rest of the body is two to three times as great as in fasting animals. It has also been found that in animals maintained on a high protein diet, various globulin and albumin fractions of the liver protein are increased 50 to 60 per cent over controls (Luco, 1936).

Unfortunately the modes of storage and release of protein are almost wholly unknown. There is evidence that protein is stored in other places than the liver and also that the thyroid gland exerts an important control. Thus the edema of the myxedema resulting from hypothyroidism may be an exaggeration of the deposit of protein in and beneath the skin. The effect of thyroxine in reducing the increased proteins of the tissues in cases of myxedema supports the view that the thyroid gland is somehow associated with protein regulation and metabolism. The increase of fibrinogen in the blood when adrenaline is injected, indicates that the sympathico-adrenal mechanism may affect storage of that protein, for it is known to come from the liver (Riecker and Winters, 1931).

Fat. Although the concentration of fat, cholesterol and lecithin in the blood is fairly constant in the same species of animals, it may differ greatly in different species. To be sure, the ingestion of fat produces an alimentary lipemia, in which the fat content of the blood may rise as high as 2 per cent. A relatively large increase in the concentration of fat in the blood appears to be without serious consequences. In pathological states, as for example in diabetes, the lipemic percentage may rise to 10, 15 or even to 20 per cent without producing obvious symptoms. On the other hand, normal blood fat is remarkably persistent. Whether carbohydrate and protein alone are fed for considerable periods or there is an experience of fasting, the lipemic level may undergo no downward change. Indeed, in a short fast the level may actually rise before it undergoes a gradual descent.

The relative constancy of the lipemic level for many days in spite of complete starvation implies a governing agency which brings fat from storage into the blood stream. Fat is stored in the cells of the liver if carbohydrate is not fed; it is also stored in adipose tissue under the skin, beneath serous coats (*e.g.*, around the kidneys), in the omentum and between and in the muscle fibers. Excessive intake of any of the foodstuffs may lead to excessive fat storage. In hypothyroidism and also after lesions in the neighborhood of the pituitary gland there is an abnormal adiposity. The manner in which these two glands may affect control of the obese state is unknown.

If the regulation of fat storage is obscure, the regulation of its release is even more so. Recent studies have shown that the stores are not fixed but are being continuously broken down and renewed. Certainly when fat is needed to maintain the energies of the body it is removed from adipose tissue until the fat cells are practically empty. It is possible that a reversible reaction mediated by tissue lipase is an important factor in maintaining homeostasis of the lipemic level—the enzyme favoring storage when the level is raised and favoring release when the level falls.

Calcium. Calcium has many diverse functions. It is used for the growth of the skeleton and the teeth, for the repair of broken bone, for maintaining proper conditions of irritability of nervous and muscular tissue, for the coagulation of blood, and for the production of milk. Like sugar and protein and fat, calcium may be in great demand on exceptional occasions, some of which have just been indicated. In such circumstances, however, the amount in the blood must not be reduced, for serious consequences ensue. Normally the calcemic concentration is held at approximately 10 mgm per cent; a variation to half that percentage may be accompanied by convulsions, and a variation to twice that percentage may be accompanied by greatly increased viscosity of the blood. Obviously, homeostasis of blood calcium is of capital importance. As with other substances useful in the organism, the homeostasis of calcium is made possible by storage in times of abundance and release from storage in times of need. Calcium is stored in the trabeculae of long bones; these trabeculae may be made to disappear by a persistent diet deficient in calcium and by growth. They are readily restored, however, by feeding a calcium-rich diet (Bauer, Aub and Albright, 1929).

How the homeostasis of calcium is regulated has not been determined, though the parathyroid glands are surely involved. Thus partial or complete removal of these glands results in a reduced calcium content of the blood, in defective deposit of dentine in growing teeth, and in a failure of proper development of a callus around a bone fracture. Again, a diet poor in calcium induces parathyroid hyperplasia. The stress of pregnancy and lactation does likewise, without, however, reducing the calcium percentage in the blood. Furthermore, diseases which are characterized by defects in the calcification of bone (for example, rickets and osteomalacia) are attended by hypertrophy of the parathyroid glands. Finally, experiment has shown that the implantation of parathyroids in a parathyroidectomized rat restores the power to deposit dentine having a normal calcium content. Unfortunately the manner in which the parathyroid glands control the homeostasis of calcium is still unknown.

The pharmacodynamic action of thyroxine seems to implicate the thyroid as well as the parathyroid glands in calcium metabolism, for administration of that agent greatly increases the loss of calcium from the body by the excretions. There is also evidence that in hyperthyroidism, bones develop a porous condition and that calcium excretion is much augmented.

Homeostasis by Overflow

The use of overflow as a means of checking an upward variation of constituents of the blood has been mentioned. Not only excess glucose but also excess water and excess sodium and potassium and chloride ions are discharged through the kidneys. These are all "threshold substances"—they are resorbed by the kidney tubules to a greater or less degree.

It is interesting to note that these substances are primarily stored by flooding or inundation. When the supplies are adequate, however, the ability of the overflow factor to maintain homeostasis in spite of excessive intake is little short of marvelous. The feat of drinking 5.5 quarts of water in 6 hours—an amount more than 33 per cent greater than the estimated blood volume, passed through the kidneys with such nicety that at no time was the hemoglobin percentage observably reduced—is a

revelation not only of the efficacy of the kidneys as a spillway but also of the provisions in the body for the maintenance of constancy of its fluid matrix (Haldane and Priestley, 1915).

The lungs as well as the kidneys serve for overflow. A slight excess of carbonic acid in the arterial blood is followed by greatly increased pulmonary ventilation. The extra carbon dioxide is thus so promptly and effectively eliminated that the alveolar air is kept normally constant. By this means extra carbon dioxide resulting from bodily activity flows out from the blood over a dam which is set at a fixed level. In consequence, the hydrogen-ion concentration of the blood is, in normal conditions, fairly evenly maintained and the harmful effects of an excessive shift are avoided in either the alkaline or the acid direction.

Homeostasis by Regulating Processes

There are homeostatic conditions which, though involving the use of materials, are so much more dependent on altering the rate of continuous processes that they can reasonably be placed in a separate category. The maintenance of neutrality and the maintenance of uniform temperature (in homeothermic animals) will illustrate the methods.

Maintenance of Neutrality. The hydrogen-ion concentration in the blood is determined by the ratio of H_2CO_3 to NaHCO_3 . On going to a high altitude the tension of carbonic acid is lessened; thus the ratio is lowered and the pH rises. In these circumstances the blood alkali also is lessened until the normal pH is restored. On returning to sea level the opposite process occurs and continues until the usual relations are restored—due probably to the passage of acid substances from the blood into the tissues or out through the kidneys.

As is well known, accumulation of the acid metabolites, which are continuously being produced in living cells, would interfere with or actually prevent continued functioning. That contingency is avoided by elaborate arrangements. The lactic acid, for example, which is developed in muscular contraction, is in part promptly neutralized; another part is soon oxidized; and the rest may be rebuilt in the liver into neutral glycogen. For continued effectiveness of these methods of disposal an adequate supply of oxygen must be provided.

Muscles and probably other tissues are able to go into "oxygen debt" by action in spite of accumulating lactic acid. That state, however, is characterized by a diminished capacity to do work, by a limitation on the amount of debt allowable, and by a definite necessity of ultimate payment. An oxygen debt can be avoided if the non-volatile lactic acid is burned to volatile carbonic acid; the volatile acid can be carried away and disposed of to an almost unlimited amount with only a slight change in the reaction of the blood. Obviously, therefore, during vigorous muscular work, when the production of lactic acid is great, as much oxygen as possible should be delivered to the active tissues. Probably because air-breathing animals are surrounded by an unlimited supply of oxygen there is practically no store of it in their bodies. The problem, therefore, is that of conveying as much as possible of the boundless external supply to the needy tissues. For that purpose the continuous process of respiration and the circulation of the blood must be greatly accelerated. The adjustments required to rid the body of the volatile acid waste are, by good fortune, precisely those required to bring to the tissues the oxygen which serves to make the acid volatile and thereby readily discharged.

In vigorous exercise the pulmonary ventilation may be increased from 10- to 13-fold, due to the stimulatory effects of acid on the respiratory mechanisms. Also the return of blood to the heart per minute is greatly augmented by contraction of the abdominal vessels, by pressures rhythmically exerted by the laboring muscles on the capillaries and valves in the veins within them, and by pumping action of the diaphragm. The heart, more amply charged with blood, puts forth a greater volume

per beat, and because of adjustments through the nervous system it may beat more than twice as fast as it does when at rest.

The larger cardiac output of blood per minute meets a constricted splanchnic area, and the result is a marked rise in arterial pressure. In the laboring muscles, arterioles are dilated and the capillaries, many of which have been closed, are abundantly opened; through these dilated and more numerous channels the high head of arterial pressure drives a rushing stream of blood. The total circulation rate may be augmented as much as 4-fold. Not only are the respiratory gases conveyed more effectively by rapid movement of the red blood corpuscles, but the conveyance of these gases is also increased by a release of extra corpuscles from storage in the spleen (Barcroft, 1926). Contraction of the spleen, like constriction of the splanchnic area and acceleration of the heart, results from operation of the sympathetic system. Furthermore, in the laboring muscles where acid is being produced and where there is special need for oxygen, the excess carbon dioxide, which results from the burning of lactic acid, itself serves to facilitate the unloading of oxygen from the red corpuscles and its carriage away to the lungs. In these ways the local blood flow in a vigorously active region may be increased as much as 9 times and the oxygen delivery may be increased as much as 18 times its amount during rest. By these admirable adjustments, lactic acid, which can be produced in a short time by muscular work to a degree which could neutralize the buffer substances in the blood, and which could induce the total cessation of muscular work, is not allowed to accumulate—indeed, the reaction of the arterial blood is altered to only a minor degree.

Maintenance of Uniform Temperature. Uniform temperature is obviously important for providing conditions favorable for a fairly constant rate of the chemical changes in the body. In normal conditions the diurnal range of temperature variations in human beings is scarcely more than 1°C . If the temperature tends to rise, relaxation of peripheral vessels exposes warm blood to cooler surroundings; and if that is ineffective, sweating occurs and the blood flowing through the skin, cooled by evaporation, loses extra heat. Panting performs a service similar to sweating, especially in animals such as the dog that are not well provided with sweat glands.

If the temperature tends to fall there is a constriction of peripheral vessels, and in animals provided with fur or feathers, an erection of these appendages of the skin which enmesh around the body a layer of poorly conducting air. When these means of conserving heat do not check the fall of temperature, adrenalin is set free in the blood stream and exerts a thermogenic influence. And if the heat thus produced does not suffice, shivering is automatically induced as a final protection against a temperature drop. These arrangements for maintaining a homeothermic state involve only acceleration or retardation of processes which are constantly going on.

Recent evidence has shown that in the subthalamus there are two thermostatic regulators; one of them is brought into operation when the temperature tends to rise, the other when the temperature tends to fall (Ranson, 1936). The regulation can be influenced directly by the temperature of the blood and also reflexly. The noteworthy features of the complex of arrangements are the varieties of bodily devices for the maintenance of thermo-homeostasis, their appearance in a sequence of defenses against change, and the intimate involvement of the sympathetic system in the conservation, production and dissipation of heat.

Role of the Autonomic Nervous System in Homeostasis

For the most part, the regulation of steady states in the blood is not under voluntary government. Commonly the autonomic system, or that system in coöperation with endocrine organs, is called into action. Illustrations of these facts are found in the vago-insular and the sympathico-adrenal influences on the glycemie level, the vagal and sympathetic effects on the heart rate and the sympathetic effects on blood

vessels during vigorous muscular effort, and the sympathico-adrenal function in accelerating heat production when the body temperature tends to fall (cf. Cannon, 1939a).

The nervous system produces its effects in two relations. It operates on the muscles which move the bony levers and thereby changes the external environment or the position of the organism in that environment, as in laboring, running or fighting. These may appropriately be regarded as exteroeffective activities.

The other relation of the nervous system is toward the internal environment, i.e., toward inducing changes in the heart, in smooth muscles and glands such as to preserve a fitness of the internal environment for continued exteroeffective action. Inactivity of the exteroeffective system establishes a basal state for the organism because minimal functioning of that system is accompanied by minimal functioning also of the interoeffective system. When exteroeffective activities produce changes in the internal environment, e.g., by utilizing blood sugar or by discharging into the blood acid waste and extra heat, the interoeffective system is set in action to correct the alterations; when they are corrected its activities subside. Thus the two parts of the nervous system—the exteroeffective and the interoeffective—are engaged in close coöperation.

Although the cranial division of the autonomic system may be regarded as concerned with the upbuilding of reserves, e.g., in promoting gastrointestinal movements, in secretion of digestive juices and thereby in storage of provisions and materials for bodily use, it is the sympathetic division which is the main agency for mobilizing bodily forces for action or correcting the alterations produced by varying internal or external conditions. By mobilizing reserves and by altering the rate of continuous processes, this division works to keep constant the fluid matrix of the body, and may properly be regarded as the special and immediate agent for control of homeostasis.

The Causes and Nature of Cancer *

LEO LOEB

Washington University, St. Louis, Mo.

Introduction

Tumors in general, and malignant tumors in particular, were first studied by pathologists and clinicians as the cause of disease and death in man. A tumor, in the specific sense in which this term is now used, means an abnormal, localized condition in the body, characterized by an increase in the number of cells or in intercellular substances, or both; in some cases, the number of cells, and in others, the quantity of intercellular substances preponderating. Tumors may be classified as benign or malignant. Benign tumors have slow growth, which may come to a standstill after some time, and they remain localized; if they produce injurious effects, these are largely due to the pressure they exert on neighboring tissues or organs. Malignant tumors, which are called cancers, grow more rapidly than benign tumors. Their growth consists in a multiplication of cells which are essentially of the same type as those of the organ or tissue in which they originate, such as the epidermal cells of the skin, the cells of the intestinal surface epithelium or glands, the specific cells of the liver or thyroid acini, and so on; or they may originate in the connective tissue cells of the stroma of these and other organs, or in the cells of bone and cartilage. Also, the endothelia of the blood vessels and components of the nervous system may give origin to both benign and malignant tumors. The growth of the latter is usually so rapid that the conditions are unfavorable for the production of specific intercellular structures.

Cancers differ from benign tumors not only in their more rapid growth, but also in the manifestation of structural abnormalities. The relation of the proliferating cells to stroma and blood vessels may be altered as the result of the more rapid growth; thus, instead of a single layer of glandular tubular or acinar epithelium, the proliferating epithelial cells may produce strands of cells, which show an irregular arrangement. There is usually associated with the increase in cell multiplication an increase in ameboid motility of these cells. As the result of both the increased proliferation and movements, cancerous cells infiltrate the neighboring tissues and destroy them. They may penetrate into blood vessels as well, especially into veins and into lymph vessels, and be carried with the blood or lymph stream to distant organs. If in these they are held back by mechanical factors, they may settle, multiply, and give origin to secondary cancers, which closely resemble the primary tumors and are called metastases. Occasionally there may be found transitional stages between benign and malignant tumors, as, for instance, tumors which have the main characteristics of benign growths but which give rise to metastases.

All kinds of cells can give origin to tumors, including cancers, provided they have the power to propagate. The large majority of the cells composing the various tissues and organs possess this power, but certain cells which represent endstages of differentiation have lost it, such as the polymorphonuclear leucocytes or the ganglia cells of the adult organism, although the precursor cells of the leucocytes, as well as the embryonal ganglia cells, still have the ability to proliferate and to produce

* Written with the aid of a grant from The International Cancer Research Foundation.

tumors. If tumors found in postembryonal life consist of cells which proliferate only during the embryonal period, it may be assumed that such tumors have developed from embryonal tissues.

Both benign tumors and cancers are classified according to the organs and tissues from which they originate. The principal types of cancers are carcinomas, derived from epithelial tissues, and sarcomas, the offspring of connective tissue cells. Carcinomas and sarcomas, as well as benign tumors, are further subdivided in accordance with the special tissues and organs from which they are derived.

The large majority of cancers develop during later adult life. As a rule, they increase in frequency with increasing age, but malignant tumors of certain organs have a maximum incidence at an age which is influenced by the activity curve of the given organ in its interaction with other organs. In certain organs the incidence may, therefore, decrease again in old age. Other cancers, whose origin can be traced to abnormalities developing during embryonal life, may start during the intrauterine growth phase, although they may become manifest only in postuterine life. Likewise, benign tumors may begin to develop before birth.

Clinicians and pathologists have studied the origin and growth of various types of tumors, their structural behavior, and their effect on the health and metabolism of the patients, and pathologists in particular have described the characteristics of the cells and intercellular substances of a great many of such tumors in order to trace their origin from certain tissues,

This constitutes the clinical and descriptive morphological phase in the study of tumors. While this phase continues today, there have been added to it during the last fifty years experimental investigations into the biology and biochemistry of tumors. With the introduction of the experimental method, new problems arose, in which cancerous growth was no longer considered of clinical concern only, but also of general biological significance and interest; compared with other types of growth, such as embryonal, regenerative and hormonal-correlative growth, this study suggested the analysis of the relations of various chemical and physical agents which are growth stimulators to the substratum on which they act.

Transplantation of Tumors

The earliest experimental procedure which greatly extended our knowledge of the cancerous process, was the transplantation of tumors in animals, and the first successful transplantations were carried out by Hanau, Morau, Velich, Eiselsberg and Firket. These investigators used for this purpose carcinoma in the rat and mouse, as well as sarcoma in the rat. These experiments established the fact that certain tumors can be transplanted to other animals of the same species, at least for a limited number of generations. In the beginning of this century, consecutive transplantations of sarcoma of the thyroid gland of rats by the writer (1901) and of a mammary gland adenocarcinoma of the mouse by Jensen (1902), which extended through many more generations, were first used as a method for the analysis of the characteristics of the tumor cells and of the interaction between tumors and hosts; there was thus initiated the experimental study of the biology and causes of cancer, which has continued with increasing intensity until the present day.

It is possible to excise and transplant normal adult tissues to other positions in the same organism or to other organisms belonging to the same species. However, the transplantability of normal tissues is very restricted, being limited by the genetic relationship of the donor of the transplant and the new host and of their individuality differentials. The results of transplantation of cancers depend likewise upon the relationship between the individuality differentials—and organismal differentials in general—of host and transplant, but transplantation of cancer differs from that of normal tissues in several important respects. While many normal tissues as well as almost all cancers can be transplanted into individuals in which the individuality

differentials have become very similar as the result of long-continued close inbreeding or of certain other conditions, the growth of grafted normal tissues is very limited in contrast to that of grafted cancers, which latter, as a rule, continue to grow after transplantation at least as actively as the original cancers; they can therefore be subdivided into small pieces and transferred from generation to generation into many animals in an unending series. Furthermore, there are certain cancers which are much more independent of the nature of the individuality differentials than others; they can be transplanted even into individuals of the same species in which the individuality differentials between host and transplant differ very markedly. Great differences exist in this respect between different cancers; some can be transplanted only into a limited group of different strains, others into all or almost all strains of the same species. This remarkable degree of transplantability is partly due to the strong growth momentum of the tumor transplant, which is able to overcome obstacles to which normal tissues would succumb. This growth momentum in the case of many cancers increases in the course of the first serial transplantations, or sometimes during the later transplantations, and with this increase in growth momentum there is associated a widening in the range of transplantability. This increase, observed so frequently in the course of the first transplantations, occurs also, as a rule, if serial transplantations are carried out, for instance, with a mammary gland carcinoma originating spontaneously in a closely inbred strain, into mice belonging to this strain. Such an effect is not due to a chance selection of hosts among non-homozygous animals. In a few tumors it has been possible to carry out even transplantations serially to different though relatively nearly related species, but this succeeds usually only if the tumor is retransplanted to a new host, before immunity against the graft has fully developed in the first host. Putnoky found that a certain line of adenocarcinoma of the mammary gland of mice could be readily transplanted into successive generations of a Hungarian strain of rats. This mouse tumor possesses a very great growth momentum and this is probably one of the reasons why it succeeded in overcoming the obstacle which a heterogenous, although nearly related, species differential presented. It is probable that, in addition, processes of adaptation may have taken place in this tumor in the course of serial transplantation in the rat, but this latter process did not alter the species differential of the tumor cells, the mouse differential not being changed into that of the rat. Whether these adaptative changes, if present, consist in an increased resistance of the transplanted cells to injurious factors emanating from the host, or in a diminution in strange substances given off by the transplant and consequently to a diminished reaction of the host against the transplant, is not known. On the other hand, transplanted cancers as a rule are less invasive than the original cancers and they can be more readily removed from the host without leaving behind cancerous cells which would give rise to recurrent growths, which latter often develop in the animal in which the tumor originated even after an apparently complete extirpation.

It is thus possible to increase the growth energy of cancerous tissues by means of experimental transplantations.³⁶ Even in metastases, which represent spontaneous, autogenous transplantations, the growth energy is increased in many cases over that of the original tumor. It is furthermore possible, through mechanical means, to increase the growth energy of a tumor which has lost a part of its growth momentum, as for instance, as a result of bacterial contamination of the grafted tumor. If such a tumor is growing with diminished proliferative activity, it can, in some instances, be made to grow again more actively by excising a piece or by pulling a thread through it. Conversely, the growth energy of a tumor can be diminished experimentally in a graded manner by subjecting the excised cells *in vitro* to various degrees of heat, or by exposing them to the action of injurious chemical substances previous to transplantation.³⁶ It is then possible to raise again, by experimental

means, the growth energy which had previously been diminished; this often occurs in the course of further transplantations. In addition, it has been shown by MacDowell in the case of acute leukemia, which is a cancer of certain leucocytic cells, that the immunizing properties of cancer cells may change in the course of transplantation. While these various characteristics have so far been established only in the case of cancer cells, it is not certain that they are peculiar to these and that they are lacking altogether in normal cells; it may well be that they are potentially present also in the latter but cannot become active because of the low growth momentum of these tissues.

There are some locations in the body where the transplanted tumors in some way are more or less protected against the injurious action of heterogenous hosts, which means individuals belonging to different species. Such locations are the brain (Shirai, Murphy), and the anterior chamber of the eye (Smirnova, Greene, Saxton, and others). Tumors from distant species grow also in the allantois of the chick (Murphy). Again, this is not a characteristic of cancers, but it applies also to normal heterogenous tissues, which likewise remain alive in the chick allantois and may be somewhat better preserved in the anterior chamber of the eye than in other locations.

The fact that different types of cancer composed of diverse tissues may be transplanted indefinitely from generation to generation has led to the important conclusion that isolated tissues of mammalian organisms may have the potentiality to immortal life, although the composite organisms undergo ageing processes and invariably die. This conclusion follows, since cancers are merely transformed normal tissues and it is possible experimentally to change a normal into a cancerous tissue.^{33, 34, 35, 36, 45}

Benign tumors differ from cancerous tumors in a lesser growth energy. They stand, in this respect, midway between normal tissues and cancers. Furthermore, they lack invasive powers. Correspondingly, their transplantability is intermediate between that of cancers and normal tissues; but there are benign tumors which also can be transplanted indefinitely from generation to generation; however, under these conditions they grow relatively more slowly than cancers, and in contrast to the latter, they may still be accessible to the action of hormones produced by their hosts or introduced into the hosts from the outside. Cancerous tissues as a rule can no longer be influenced by hormones, but some variations may perhaps exist in this respect in the case of certain malignant tumors.

The ability to undergo permanent growth, with increase in mass, after transplantation into other individuals has been made use of in order to recognize whether a normal tissue, subjected to certain cancerigenic stimulations, had become converted into fully cancerous tissue, in which case it would continue to grow in a cancer-like manner in the new host after cessation of the original growth stimuli which had induced the cancerous state. On the other hand, tissues which merely simulated cancerous growth, or which had not yet fully reached the cancerous state, would cease to proliferate in the typical cancerous manner after transplantation, since it is one of the characteristic features of cancer that if this stage has once been attained tissues may die under unfavorable circumstances, but, as far as is known, they do not return to the state of normal tissues. However, as a rule it is not necessary to have recourse to such a method for the diagnosis of malignant tumors, because this can be made by the observation of an irregular structure and mode of growth and of invasive activities.

Cancerous tissues during the process of serial transplantation can be seen to grow as the result of the continued multiplication of their own cells; they do not commonly transmit their cancerous characteristics to the neighboring tissues with which they come in contact. But such a transmission of cancerous properties has been observed in some cases, in which transplanted carcinomatous tissue converted the stroma with which it came in contact into a sarcomatous tumor. In addition,

there is some evidence that a carcinomatous tissue under exceptional conditions may change also adjoining normal epithelium into carcinoma. We must assume that the cancerous tissue exerts this effect on the neighboring cells through some substance which it gives off; but as to the nature of this substance, nothing is known at the present time. In the center of the transplanted, as well as of spontaneous, cancers, the tissue often degenerates and dies, because of the insufficient circulation at a distance from the periphery of the tumor.

We have already mentioned that cancer cells may elicit in the host immune reactions which are injurious to the cancerous transplant, and either prevent its full development after transfer of the cancer cells into a new host or cause their retrogression after they have established themselves and have grown vigorously for some time. Such immune processes may occur also as a result of the active growth of a first tumor, which prevents a second implanted tumor from growing, or they may develop after extirpation of a first, strongly growing tumor which had the ability to neutralize the immune mechanisms developing in the host as a result of this growth (Uhlenhuth's phenomenon). Another type of active immunity may develop after implantation of various normal tissues which belong to the same species as the tumor cells and the host. Identity of the species differential of the tumor and of the immunizing tissue is necessary for the establishment of this type of immunity, but implantation of tissue possessing the same individuality differential as the host is unable to cause immunization. There has been much discussion as to the mechanism underlying these types of immunity against cancer. Do they depend upon the development of antibodies which can be transferred to other hosts, which are thus made passively immune? It has not been possible to demonstrate such a passive immunity in a clear cut way. Nevertheless, there are experimental indications that substances are present in the bodyfluids of the immunized host which injure the transplant (Woglom).⁹⁸ In addition, the transplant is injured as a result of cellular reactions, in which lymphocytes, blood vessels and connective tissue may participate. While immune processes are most striking in the case of cancerous tissues, they are not limited to or characteristic of the latter; they may be demonstrated also in the case of implanted embryonal tissues, and even transplanted normal adult tissues may induce certain immune reactions against normal tissues transplanted subsequently (Blumenthal). While this type of immunity is directed against the individuality or species differentials of the transplants, there is evidence that an immunity may develop also against substances which are distinct from these differentials but are characteristic of certain types of cancer.

It is an interesting fact, observed by Loeb and Fleisher, and more recently by Blumenthal, that spontaneous tumors of the mammary gland of mice, which as a rule cannot be transplanted into mice belonging to strains other than those in which they originated, can be successfully transplanted in a considerable number of cases into such animals if they are bearers of spontaneous tumors. There must, here, be active some factor which counteracts the effects of the strange strain differential, which is unfavorable to the long-continued life and growth of the grafted tissues. Whether this is a growth-promoting substance or a mechanism counteracting immunization against the transplant has not yet been determined.

Transplantable tumors present a material favorable for attempts to separate, if possible, from tumor cells microorganisms or viruses able to induce tumor formation if injected into susceptible animals. Early experiments of this kind by the writer and Maximilian Herzog showed that with rat sarcoma, only injection of macerated tumor tissue, passed through filters which permitted also cells to pass through the pores, gave origin to tumors, whereas the filtrate from Berkefeld filters, which was free of cells, was ineffective. Similar results were obtained with all other mammalian cancers which have been tested so far, and also with the leukemic tissues or cells from mice affected with this tumor-like condition. However, when Ellermann

(1908) in the case of avian leukemia, and especially Peyton Rous (1911) in the case of various types of fowl sarcomas, carried out similar experiments, they succeeded in separating from the tumor cells a filtrate which, on injection into other chickens, stimulated leucocytes to become leukemic or mesenchymatous cells, especially those which were actively proliferating, to give origin to sarcomata composed of the same type of connective tissue which characterized the original tumor. These experiments of Rous, which have proved very fertile, have since been confirmed by Fujinami in Japan and by many others. It is furthermore possible to produce neutralizing antibodies and precipitins against this agent. Murphy and his collaborators, Claude and Sturm, purified the sarcoma filtrates or desiccates and studied the physical and chemical characteristics of these substances. They found that after purification, the active constituents of these filtrates no longer were able to produce antibodies. As to the nature of the agent, Claude believes that it is a phospholipid-ribonucleo-protein complex, similar to that which constitutes the mitochondria of cells. Further investigations must show whether the particles separated by the ultracentrifuge and resembling mitochondria in size and constitution are the real agents of chicken sarcoma, or whether they are the substratum to which the real agent adheres. Jobling, Schemin and Sproul obtained an active substance showing qualitatively a similar constitution to that found by Claude. These investigators, as well as Beard, believe, therefore, that the agent causing the formation of chicken sarcoma is a very complex, non-living substance.

As to the heterogenous transfer of Rous chicken tumor I, either by injection of the virus-containing tumor extract or by transplantation of minced tumor tissue containing cells, Murphy and Rous first found that this chicken tumor I could develop in the allantois of chick embryos, but transplantation into adult ducks did not succeed. Purdy was not able to infect ducks or ducklings with such tumors by injection of large amounts of virus-containing extracts from a Rous or an endothelial chicken tumor, but by transmitting great quantities of minced tumor tissue, he could transfer Rous sarcoma through several generations of ducklings; however, this could be accomplished only if very young ducklings were used—the tumor could not be transplanted into adult ducks. Des Ligneris likewise had negative results when he used adult ducks and geese, but he succeeded in transferring the tumor to turkeys and guinea fowls.

If the Fujinami fowl sarcoma was used instead of Rous sarcoma I, the results were more favorable. Fujinami transferred this tumor through 40 generations of ducks. Gye, by means of filtrates or of cell suspensions, could transfer the same tumor serially to ducklings, but in half-grown or adult ducks the tumor could grow only for some time and it later regressed; however, Purdy succeeded in transmitting it serially to ducklings, and even to adult ducks, by injecting very large amounts of minced tumor tissue. A chick in which such a tumor happened to regress, had thereby acquired an immunity against a Fujinami tumor but not against a Rous tumor.

In general, it may then be concluded that fowl sarcoma can be transferred much more readily to newly hatched, heterogenous birds than to somewhat older ones: with increasing age, the transmission becomes more difficult. However, different types of fowl tumors differ in their ability to grow in heterogenous hosts. In this connection it may be stated that also normal tissues are tolerated better in very young hosts than in older ones. Moreover, different races of a certain avian species differ in their suitability as hosts. This transfer of avian tumors can be accomplished by means of tumor extract (virus) as well as by means of tumor cells; but the latter on the whole seems to be more successful, especially if large quantities are used. A transfer of these tumors into more distant species, such as mammals, does not succeed.

Quite recently, Duran-Reynals has shown that if we transfer Rous fowl sarcoma

I to ducklings, at first the unchanged chicken tumor virus or cells cause the tumor development in these ducklings, as indicated by the fact that the tumors thus produced have not only the same morphological characteristics as the chicken tumor, but they have also the same tissue affinities and the same tendency to be localized. However, after the tumors have lived for some time in ducklings, they may change their characteristics, the chicken-adapted virus becoming a duck-adapted virus; it then tends to cause sarcomas in different organs, such as bones or lymph glands, calling forth a lymphosarcoma in the latter organ. This changed tumor also tends to be generalized. A similar adaptation seems to occur if cells are inoculated; these also cause the same kind of tumors as the duck-adapted virus. Such a duck-adapted virus or cell suspension not only causes tumor development in ducklings, but also in adult ducks. Cells and virus are now no longer heterogenous but homogenous for the duck. If such duck-adapted virus or cell suspension is transferred into chicken, it seems at first to behave like material heterogenous for the chicken, but after some time the duck-adapted virus or cell suspension can again become chicken-adapted, being converted into a homogenous virus. However, it cannot very well be concluded from these experiments that a chicken cell was actually changed into a duck cell, but merely that the changed virus altered at the same time the tumor-producing characteristics of the chicken cells in which the virus lived. It has also been found by Duran-Reynals that the Rous chicken sarcoma I virus may, occasionally, instead of giving rise to tumors, produce a generalized hemorrhagic disease. We have discussed these conditions somewhat more fully, because they are of importance also as far as the problems relating to the causes of cancer in general are concerned.

From this brief resume, it may be seen that by means of the method of transplantation of tumors many interesting facts have been established, which are not only of great significance from a biological point of view, but which have also contributed much to the understanding of the nature of tumors.

The Biochemical Constitution of Cancer Tissues

Cancer tissues have acquired certain new characteristics which differentiate them from normal tissues and also from various other types of growing tissues, as, for instance, those undergoing correlative, hormone-stimulated growth. The increased growth of cancer cells is a permanent characteristic and not a transitory condition, as is the growth of non-cancerous growing cells. We may now inquire whether in addition to these growth and structural differences between cancer and normal tissues there exist also differences in their biochemical constitution and metabolism.

Several interesting differences of this kind have been reported; we shall consider here only the most important ones. In 1926, Warburg observed an altered carbohydrate metabolism in malignant tumors. Oxidative processes were diminished and aerobic as well as anaerobic glycolysis was increased; lactic acid was produced mainly by the splitting of sugar instead of CO_2 by oxidation. The behavior of benign tumors was midway between that of normal and of cancerous tissue. It was found, however, that glycolysis was also increased in the retina, in embryonal tissues, placenta (Murphy), regenerative tissue (Pentimalli), and leucocytes. Moreover, Murphy and Hawkins, as well as others, observed that in malignant mammary gland tumors of the mouse, glycolysis tends to be low or zero. According to Berenblum, even normal skin may behave like malignant tumor tissue in this respect. On the other hand, Dickens and Burk support the view of Warburg that the carbohydrate metabolism of malignant tumors is specific. They consider a relatively low respiratory quotient, together with very high anaerobic glycolysis, as characteristic of tumor metabolism. The increase in aerobic glycolysis is held by Burk to be a secondary condition, due to the fact that notwithstanding an active Pasteur effect, anaerobic glycolysis is so strong in malignant tumors that the respiration in many

cases cannot prevent glycolysis even under aerobic conditions. In mouse leukemia, Hall and Furth find that the oxygen consumption and the Pasteur effect are normal, and that the rate of aerobic glycolysis is not increased in contrast to the anaerobic glycolysis, which is higher in leukemic than in normal lymph nodes. Regenerating or embryonal tissue, like tumor tissue, shows a high anaerobic glycolysis, but this is to some extent compensated by a strong respiration. While in normal tissue the respiration is below that of noncancerous but growing tissue, the anaerobic glycolysis is here also relatively low. The chicken sarcomas caused by a filtrable virus possess the same carbohydrate metabolism which is characteristic of other malignant tumors; the agents transmit therefore, to the normal cells in which they live and multiply, the metabolic characteristics of cancer cells. On the other hand, it seems that the cells of fowl leukemia, which is likewise caused by a filtrable virus, do not possess this type of carbohydrate metabolism.

We may then conclude that while the carbohydrate metabolism of cancer cells shows certain peculiar properties, which, in a general way, distinguish them from other types of cells, the degree to which these distinguishing features are developed differs apparently in different types of tumors and in different species. There occur also variations in the intensity of the oxidation processes of different types of tumors. Aerobic glycolysis is less pronounced, or may be lacking entirely, in the breast carcinoma of mice, while it may be marked in rat and human tumors, and also in chicken sarcomas. Moreover, in certain normal cells, such as monocytes, the carbohydrate metabolism may be similar to that of cancerous tissues. Notwithstanding the utilization of oxygen in the Pasteur reaction by cancer tissue, it seems that the oxidation-producing cytochrome C system of this tissue is diminished. These alterations in the tumor metabolism may occur either at the time of the conversion of non-cancerous into cancerous tissue or shortly preceding this change.

These data suggest that this change in the metabolism of cancer cells is not the cause of the cancerous process and, perhaps, not even directly connected with its essential cause. It seems more probable that it is one of the results of the cancerous transformation and possibly due to secondary conditions. Moreover, this type of carbohydrate metabolism is present in various kinds of cancer to an unequal degree, and a condition similar to it, although perhaps not identical with it, may be found also in certain noncancerous tissues.

An alteration in the chemical constitution of tumors which aroused a great deal of interest was announced a short time ago by Kögl and Erxleben (1939). They found in protein hydrolysates of malignant tumors a considerable amount of glutamic acid and smaller percentages of certain other amino acids in dextrorotatory form, while in normal tissues only the levorotatory stereoisomers occur. However, other investigators were unable to confirm these observations. Still more recently, West and Woglom found that the amount of biotin, a vitamin which is required for the growth of many microorganisms and also of higher animals, is different in cancers and in the corresponding normal tissues, and this variation seems to be in the same direction in which embryonal tissues differ from normal tissues in this respect. In some cases the development of cancer in a certain tissue leads to an increase in the biotin content, but in the normal adult liver, heart and kidney the biotin content is greater than in the embryonal tissues, and greater likewise than in cancerous liver tissue. It is conceivable that liver, heart and kidney, in addition to functioning active biotin, contain a certain amount of inactive biotin serving as reserve material, and that this may explain the different conditions found in these various organs. This biochemical difference from normal tissues is not, therefore, characteristic of the malignant state as such, but it is shared by growing tissues of an embryonal nature. However, still more recent data published by West and Woglom seem to indicate that the biotin content of tumors may be intermediate between that of embryonal and normal tissues, or that it may be lower than either

adult or embryonal tissue, although in one instance it was equal to that of adult tissue. These investigators moreover found the interesting fact that two transplanted mouse sarcomas are able to grow actively in mice depleted of their biotin content by avidin administration; these sarcomas themselves are very poor in biotin. Sarcoma cells thus seem to differ markedly from normal cells, which need biotin for their functioning. Shifts in the biotin content, when the normal tissue passes into the cancerous state, may be the consequence rather than the cause of the cancerous transformation. Furthermore, the biotin content of the Shope papilloma does not increase at the time when it undergoes a cancerous change. Young transplanted carcinoma of the liver in mice has a biotin level similar to that of the normal liver in this species. These data indicate that biotin does not play a significant role in the origin of tumors. However, it seems that biotin may, perhaps indirectly, favor the development of cancer at least in one particular instance; this would follow from the observation that administration of casein, with the addition of cystine and choline, protects rats against the formation of cancer in the liver, which otherwise would be induced by butter-yellow feeding. However, after the addition of biotin to the diet of such rats, the protection was lost or diminished and hepatomas developed in a number of animals.

In tumors, a number of different enzymes occur, and among them, catalase, arginase and amylase. It is of some interest that as a rule in tumor-bearing rats and mice the liver catalase activity is lower than in normal animals, and this change in the amount of liver catalase is proportional to the rate of the growth intensity of the tumor (Greenstein and Andervont).

Vitamin C (ascorbic acid) seems to be increased in tumor tissue as it is in some other actively growing tissues, and according to Lasnitzki and Brewer, the ratio between the isotopes of potassium $K_{30}:K_{41}$ is somewhat different in tumors from that in normal tissues. As to the significance of these differences between the biochemical constitution of tumor and of normal tissues, it seems doubtful whether they are connected with the factors leading to cancer formation; it seems more probable that they are the consequence of the cancerous growth processes directly preceding the initiation of the cancerous growth. To decide this question, it would be necessary to compare the changes found in the chemical constitution of cancer cells with the alterations in the chemical constitution which are noted in the various noncancerous growth processes.

There is one particular type of cancer, namely, the experimentally produced hepatoma of rats, in which biochemical processes which influence the initiation of this kind of growth have been studied more recently. This carcinoma in the liver of rats can be produced by oral administration of *o*-aminoazotoluene (Sasaki and Yoshida), or of dimethylaminoazobenzene (butter yellow) (Kinosita); the latter substance is somewhat more effective than the former. The liver tumor develops only if the rats are kept on an inadequate diet of non-polished rice. When butter yellow is used, cirrhosis and cholangioma formation usually precede the development of hepatoma, while *o*-aminoazotoluene may induce the formation of hepatoma directly, without a preceding cirrhosis and with or without formation of cholangioma. Rhoads and his collaborators have found a deficiency of coenzyme I and of riboflavin in this kind of tumor. Several investigators have observed that various supplements to the rice diet may diminish or prevent the appearance of this type of cancer. Such supplements are yeast, liver, kidney, ricebran oil, and various extracts of yeast, ricebran or liver. If a combination of riboflavin and casein, or of the vitamin B complex and cystine and choline was added to the rice diet of rats to which butter yellow was administered, carcinoma of the liver did not develop. A substitution of wheat, rye or millet for the rice diet likewise decreased the cancerigenic action of butter yellow and of *o*-aminoazotoluene. Kinosita and Rhoads, Stevenson and Dobriner have studied the split products found in the urine of rats fed with butter

yellow or *o*-aminoazotoluene; there was an indication that it is some of these secondary substances which have the cancerigenic effect, and as stated, Rhoads and his associates suggest that this effect consists in an interference with coenzyme I, and perhaps also with the riboflavin present in the normal liver cells. However, the outcome of further investigations must be awaited regarding these problems.

There is still another method suitable for the study of specific chemical constituents in cancer tissue, if such should exist, namely, the production of antibodies against cancer. Specific substances present in the cancer cells might function as antigens and induce the production of immune substances in animals belonging to different species (rabbits). The interaction of the antigens with the immune substances (antibodies) in the blood serum of the animal injected repeatedly with cancer cells or their constituents might be recognized by precipitation, agglutination, complement fixation, anaphylaxis, or otherwise by neutralization of the specific antigens. In other investigations, the blood serum of a person or animal affected with cancer has been mixed directly with a tumor-specific antigen, in order to demonstrate the presence of an antibody preformed in the blood serum of such an organism. Experiments of the former or latter kind have been carried out especially by Hirszfeld and his collaborators, by Lehmann-Facijs, Lumsden, Kidd, Dmochowski, Welker, and a number of other investigators. Their results agree in that there is noted in cancer tissue the presence of certain antigens not present in normal resting adult tissues; but there are differences between the conclusions arrived at by these investigators as to the degree of specificity and as to the nature of these antigenic substances.

Hirszfeld and Halber found that a complement fixation reaction takes place when alcoholic extracts of human cancer, to which cholesterol has been added, are tested with sera of persons affected with cancer. However, this reaction did not occur with every serum and it was observed occasionally also in sera from patients suffering from other diseases and those from pregnant women. Hoyle, on mixing lipid antigens extracted from transplanted mouse tumors and the sera of mice bearing these tumors, obtained complement fixation reactions. But according to Hirszfeld and Halber, also immune sera against rat embryo extracts may react with alcoholic extracts of human cancers, and immune sera against extracts of normal rat organs reacted in some instances even more strongly with human tumor extracts than with the antigen used for the preparation of the immune sera. Conversely, immune sera against human tumors reacted also with human embryo extracts. Furthermore, antigens obtained from necrotic human tissue and from degenerating leucocytes behaved in a similar manner to antigens present in human tumors. Likewise, Dmochowski noted cross reactions when he mixed extracts of experimental (benzpyrene) rat tumors, rat muscle, or rat embryos with immune sera. On the other hand, Hirszfeld, Halber and Laskowski found similar reactions of rabbit immune sera against extracts of human cancer and against extracts of the liver of patients affected with carcinoma of the stomach.

In contrast to the results of these experiments are those of Lumsden, who observed that antisera, obtained by immunization of rabbit or sheep with human, rat or mouse cancer material, exert in vitro a specific injurious effect on cancer cells of various kinds, but not on normal tissues. This would indicate that there exist antigens which are common to all kinds of cancer, irrespective of species and tissues in which they originated. However, it seems that this specificity is not absolute, because normal spleen cells, and perhaps also spermatozoa, possess similar antigens.

Different again are the conclusions of Welker and his associates. They subjected the autolysates of cancer tissue to long-continued treatment with alumina cream and in this manner eliminated admixtures of serum proteins from this material, with which they then immunized rabbits. They thus obtained immune sera which reacted in a specific manner with extracts of cancers from the same species but not with those from a different species; in addition, these immune sera showed a

preference for extracts of cancers which originated in the same kind of tissues or organs that had served as antigens. These specific cancer antigens possess, therefore, not only species specificity, but also organ or tissue specificity, and they may be considered as modified organ or tissue differentials. However, such antisera should be tested with a still greater variety of noncancerous tissues before the conclusion as to a complete specificity of these antigens can be fully accepted.

The fact that tumors may contain antigens which are specific, differing from those found in normal tissues, and that these antigens can give rise to specific immune substances in the serum of the bearer of the tumor is indicated also by the experiments of Kidd and of Dmochowski, who found that rabbits which bear transplants of Brown-Pearce carcinoma contain in their blood serum antibodies which, when mixed with tumor extract, fix complement, while extracts of normal tissues do not have this effect. But whereas Dmochowski assumes that the Brown-Pearce tumor, as well as Murphy's liposarcoma of the guinea pig have acquired this specific antigen as a result of long-continued transplantation, Kidd believes that the antigen is a virus, which he considers as the cause of the Brown-Pearce tumor. He arrives at this conclusion because of the similarity in the behavior of the Brown-Pearce tumor antigen and the antigen from the Shope rabbit papilloma, which is known to be a virus disease. Both antigens can be filtered through Berkefeld V filters, and the serum of the rabbits affected with papilloma not only fixes complement when combined with the papilloma antigen, but in addition is able to neutralize the papilloma virus, and both these antibody effects seem to be a function of the same substance. This immune substance which thus can be used as a test for the virus may develop even under conditions when the presence of the papilloma virus in the tumor cells can no longer be demonstrated by the usual methods. In this instance, then, a specific virus would act as the specific antigen present in tumor cells and distinguishing it from normal tissues. However, while the findings in regard to the Shope papilloma antigen and antibody seem to be definite, there is apparently a certain variability as to the results obtained with the Brown-Pearce tumor, and further experiments in these directions may perhaps clear up this point. Moreover, there is the possibility that virus and antigen are not identical.

We may then conclude that specific antigens exist in tumors, differing from those obtained from the corresponding normal tissues. On the other hand, tumors possess the same individuality and species differentials as normal tissues of the individual and the species in which the tumors originated.

The Causes of Cancer

After this discussion of the most characteristic features of cancer, we may now proceed to the analysis of the factors which cause the transformation of normal tissues into cancerous growths. This transformation can be induced in all tissues which have the potentiality to proliferate, but it takes place with unequal readiness in different types of tissues in the same species and in the analogous tissues of different species. The principal factors which have to be considered as potential causes of cancer are the following: (a) The constitutional factors of the tissues of individuals and species, which are largely genetic in nature. There is, in addition, a substance which in certain strains of mice is transmitted with the milk from the mother to the offspring and which helps to determine the readiness with which mammary cancer and perhaps one other type of cancer develop in these mice; this substance is likewise hereditarily transmitted in various strains of mice. (b) Stimulating factors originating either within the organism itself or in the outer environment, which act on the cells and make them cancerous. The distinction between these two sets of factors, however, while very useful as an approximation, is not as sharply defined as it might appear, inasmuch as some hereditarily transmitted factors may function as growth stimuli, and conversely, stimulating factors may also be, at least partly,

genetically determined. As to the character of the various stimulating factors, these may differ greatly in specificity. Among the most specific ones are (1) certain viruses, (2) hormones, and (3) certain metazoic parasites; next in order come (4) tar and the so-called carcinogenic (cancerigenic) hydrocarbons, which seem to be able to act on many tissues endowed with growth potentialities, and are specific mainly because of the great intensity with which they act. The least specific factors are those which not only may affect many tissues indiscriminately, but which act also with a lesser intensity, and are well known for other effects they may exert. To this group belong various radiations (Roentgen rays, radium, ultraviolet rays), as well as ordinary chemical and mechanical irritations, usually acting over long periods of time. The hereditary genetic factors function largely by determining the degree of responsiveness of a certain tissue to the various stimuli affecting it; but in some instances they may act indirectly by inducing certain diseases, which themselves predispose to the development of cancer. In regard to the milk factor, which is especially potent in the case of breast cancer, it is not yet certain whether it acts by intensifying the response of the tissue to stimuli, thus supporting the genetic factor, or whether it functions as a growth stimulus.

We shall now discuss these various factors, although not necessarily in the above order.

(a) **Heredity in Cancer and Its Interaction with Hormones and the Milk Factor.**

All activities of living organisms are determined essentially by the inherited characteristic structure and metabolism of these organisms, and these constitutional factors are the most important ones, although they are effective only in coöperation with the environment in which the organisms live. All observations likewise show that these characteristics are hereditarily transmitted from generation to generation, in a way specific not only for each kind of organism but also for each organ, tissue and function. Cancerous growth is one of these reactions of the living substratum. In this very general sense, then, all cancers are predominantly determined by heredity. But in a more restricted sense, only conditions differential for smaller groups, such as species, strains (races) and individuals are included in the genetic analysis. We are interested in the hereditary, constitutional factors, mainly in their contrast to environmental factors, and especially we wish to compare the relative importance of these two sets of conditions. The environmental factors consist not so much in the basic conditions which affect all vital phenomena in a non-specific sense, such as oxygen, food, temperature, but above all in the specific factors, which, within a certain range, make possible the experimental control of these phenomena. Furthermore, the mode or mechanism of inheritance, expressed in terms of Mendelian genetics, has become a leading subject of scientific analysis.

The study of the significance of heredity in cancer started in a preliminary way towards the end of the last century and at the beginning of this century, but systematic investigations were begun not quite forty years ago. The first observations concerned some colonies of mice and rats, and cattle on some ranches in which certain cancers seemed to be endemic, owing to hereditary factors. Findings of this kind were made in mice and we described such observations in rats and among cattle. A number of years later, Tyzzer and the writer, and subsequently Murray in London, noted the hereditary transmission of cancer of the lung and mammary gland, respectively, among certain strains of mice. From 1910 on, in association with Abbie Lathrop, we made a systematic study of the inheritance of mammary gland carcinoma in a considerable number of strains of mice which had been inbred for a variable number of generations. It could be shown that there existed extreme differences in the cancer rates of different strains of mice; while in some of them the incidence was about 90 per cent or more, in others it approached zero, and these incidences remained approximately constant in subsequent generations, although it was possible

in some instances to develop substrains which differed in their cancer rate from that of the main strains. Not only was the cancer rate an inherited characteristic, but also the cancer age. In the majority of strains a high cancer incidence was associated with an early cancer age and a low cancer incidence with a later cancer age, indicating that a common intensity factor determined both incidence and age. But in some cases a low tumor rate was associated with an early development of the tumor, as an indication that if in a mouse belonging to such a strain the conditions for cancerous growth of the mammary gland existed, the necessary stimuli reached the threshold of effectiveness in a relatively short period of time, whereas, in some other strains the hereditary conditions for the development of cancerous growth were present in many individuals, but became manifest only if the stimuli acted over a long period of time.

If strains with a low and with a high incidence of cancer were hybridized, the parent strain with the higher rate dominated in the majority of cases; there was in successive generations of the hybrids no indication of a hereditary transmission of mammary gland cancer which would correspond to a one factor ratio, but intermediate conditions, which suggested the presence of multiple factors, were usually observed. Likewise, the great number of different cancer incidences among the different strains was favorable to this interpretation.

In addition, it was found that if mice belonging to strains with a high and with a low cancer incidence were hybridized, the cancer rate of the mother strain dominated over the cancer rate of the father strain in a considerable number of instances. This fact, taken together with several observations in which in reciprocal crosses, the hybrids, followed the tumor rate of the mother strain, suggested to us the conclusion that the mother strain may be of greater significance in determining the tumor rate of the mammary gland than the father strain.

However, it was also found in the course of these investigations that the hereditary factor was not the only one that determined the development of mammary gland carcinoma in mice, but that it needed the coöperation of ovarian hormones, and in particular, of the estrogenic hormone. By extirpating the ovaries of the mice belonging to high cancer rate strains at various periods of life, it was shown that the development of mammary gland cancer appeared the more frequently and the earlier in life the longer these hormones had had a chance to act. If these hormones had been active only during a very short period, tumors did not appear at all in the majority of strains tested, and subsequently, Cori found that in eliminating the ovarian influence still earlier in life, cancer of the mammary gland did not appear in a single case. We concluded, furthermore, that the fact that male mice were free of mammary gland carcinoma was due to the lack of the ovarian hormones in these animals. This was confirmed later by Lacassagne, who, by injecting estrogen into male mice, was able to induce cancer of the mammary gland provided the animals did not belong to low tumor rate strains. It is possible, also, that the difference in the rate of mammary gland cancer between breeding and virgin mice, which we had previously noted and which exists in a large majority of strains of mice, although it varies greatly in intensity in these strains, is due to the action of hormones given off during the period of pregnancy and lactation; however, other factors may perhaps coöperate in this condition. This was taken to indicate that the hormone, in addition to causing the transformation of normal mammary gland tissue into carcinoma, exerted still another function. Previously we had found that the corpus luteum sensitizes the uterine mucous membrane in such a way that an ordinary mechanical stimulus calls forth growth processes of a very great intensity, leading to the production of temporary tumors, the placentomata. This concept of a gradually increasing tissue sensitization by means of hormones was later transferred by us to the mammary gland of mice, where the sensitization took place under the influence of ovarian hormones. We also suggested, in the course of our earlier investigations, that the influence

of hormones in the origin of cancer may not be limited to ovarian hormones, but that different hormones may be effective also in various other types of cancer. A further conclusion which could be drawn from these experiments concerned the sensitization of the mammary gland tissue of the mice belonging to high cancer rate strains, a sensitization which took place after the hormones had been active for a certain length of time. It was found that if the hormone action was interrupted before cancer had developed, the ordinary stimuli active during the normal metabolism of the organism were able to transform, step by step, the state of sensitization which had been induced, and which could not be differentiated histologically from a non-sensitized condition, into real cancer. In conformity with this interpretation, more recently Burns and Schenken observed that if estrogen had been injected for a period of five months into male mice of a high tumor rate strain, in many animals cancer of the mammary gland developed in the course of time subsequent to the cessation of the stimulation by the injected estrogen.

Returning to the hereditary factors, Maud Slye, whose investigations followed some of those already mentioned, observed that the relative incidence of various types of cancer differs greatly in different strains of mice. There are types of tumors that are frequent in a certain strain and others that are rare, and heredity largely determines the incidence. This investigator assumed that all forms of cancer are transmitted as a single recessive factor. This conclusion is contrary to the evidence already mentioned, which points to the presence of multiple factors and of dominance rather than recessiveness; which showed furthermore that heredity is effective only in combination with factors of a different nature, a condition which complicates and renders difficult the genetic analysis of the origin of cancer of the mammary gland in mice. Conditions seem to be somewhat simpler in the case of pulmonary carcinoma of the mouse, which again is much more frequent in certain strains than in others. Clara Lynch could show that this type of cancer is transmitted as a dominant factor, and Bittner has confirmed this conclusion; but the incidence can be increased under the influence of carcinogenic hydrocarbons. In this instance, too, it has been at first assumed that a single dominant genetic factor was responsible for the hereditary transmission of this tumor, and this view is still held by Bittner at the present time. However, it seems to us that the evidence points more to the conclusion that, as regards heredity, the origin of these tumors is determined by multiple factors. Differences in interpretation which have developed are due largely to differences in the criteria used in the genetic analysis of this process. There are quantitative elements involved in the process of cancerization, the study of which in many instances has been neglected; instead, it has been considered an "all or nothing" process. If these quantitative conditions are also taken into account, a multiplicity of factors becomes the more probable assumption. Confirmation is furthermore found in the work of Andervont, regarding the grading of the cancer incidence in hybrids, in accordance with variations in the choice of the paternal strain, which transmits genetic elements but not the milk factor.

An advance in the study of these and related problems as to the origin of cancer has been made possible in more recent years by Little and his collaborators, Strong, Murray, Bittner and Cloudman, who by long-continued brother-and-sister matings increased the homozygous condition of the strains used for the genetic analysis of cancer, and in particular of mammary gland cancer. Each of these strains differs from the others in the incidence and type of cancer to which it gives origin. Because these strains are approaching—although not fully attaining—a homozygous condition, in which all individuals composing a strain have about the same genetic constitution and receive about the same amount of milk factor, it would be expected that, given the same amount of stimulation by hormones, all the mice of a certain strain should be affected in the same way with cancers; they should all acquire cancer of the mammary gland at about the same age, or should all remain free of cancer. This

is, however, not the case. These closely inbred strains behave in this respect as did the less closely inbred strains used formerly; each strain is characterized by a definite average percentage of individuals which are affected by cancer, inclusive of leukemia, and by the average age at which the cancer appears, and these figures vary greatly in different strains. However, Strong, in the case of mammary gland carcinoma, and MacDowell, in the case of leukemia, showed that if in a certain strain the cancer incidence of the offspring of mice affected by cancer is compared with that of the offspring of mice not affected by cancer, both behave in the same way; they have the cancer incidence typical of the strain. This would suggest that all mice belonging to the same inbred strain have the same genetic constitution and that the difference in the cancer rate of different individuals within the same strain must be due to non-genetic factors. But if a variety of chance conditions cause these differences in the appearance of cancer in different individuals of the same strain, it is difficult to explain why there should be such a constancy in the cancer incidence characteristic of each strain as a whole; such an explanation would postulate a corresponding constancy of the averages of these environmental factors affecting the individuals belonging to a given strain. However, it is necessary to consider also the fact that in reality none of the strains tested so far by the criteria developed for the analysis of individuality differentials has been found completely homozygous; and this fact may be responsible, at least to some extent, for these variations among the individuals of an inbred strain, although it is probably not sufficient to explain the principal data in this respect.

Reciprocal crosses between closely inbred strains with a high and a low incidence of mammary gland carcinoma made the preponderance of the mother strain, in determining the appearance or absence of cancer, more evident than it had been in the earlier experiments carried out with less closely inbred strains. In order to determine which of the non-genetic factors might be responsible for this difference in the cancer incidence found in reciprocal crosses, Little and his collaborators tested the effect of the mother's milk and of factors transmitted by uterus and placenta to the developing embryo and fetus. This was done by varying the females nursing the newborn mice and by transferring fertilized ova to the uterus of other females. In carrying out the first kind of experiments, Bittner was able to show that this difference between the effectiveness of father and mother in determining the cancer rate of the mammary gland of the hybrid offspring was due to a substance which is transmitted with the milk of the mother to the child, and which is very influential in determining this cancer rate in the offspring. The mice belonging to high cancer rate strains possess this substance in large quantities, and the mice belonging to low tumor rate strains lack the milk factor or possess it only in small amounts. This milk factor occurs, however, not only in the milk of the mothers belonging to a high tumor rate strain, but also in various organs of these mice as well as in the blood and in the cancer developing from the mammary gland. Little interprets the difference in the cancer incidence of hybrids between high and low tumor rate strains, in cases in which father or mother belong to the high cancer rate strain, as indicating that the milk factor is about ten times more effective in determining the development of cancer than are the genetic factors. However, there are indications that the genetic factors are of much greater significance than these hybridization experiments indicate. The milk factor plays such a prominent role in determining the cancer rate in these hybrids because they possess a genetic constitution which is sufficient for the development of mammary gland cancer. Under these conditions the action of the milk factor, together with that of the hormones, is the determining variable condition. But in strains which do not possess the appropriate genetic constitution, the milk factor has very little power to induce cancerous growth in the mammary gland. This holds good, for instance, in the case of strain C57, in which the genetic constitution is not favorable for the development of mammary gland carcinoma. Trans-

mitting the milk factor to these mice has only a relatively slight effect; the milk factor seems to function only if the genetic constitution is present, which permits it to act. However, it seems that the incidence of mammary gland cancer of C57 mice which have been nursed by female mice belonging to high tumor rate strains, can be increased considerably if these mice have been allowed to breed; the low incidence applies only to non-breeding mice. It is probable that this effect of breeding depends upon the increased action of ovarian hormones on the mammary gland during pregnancy and lactation, although other possible explanations exist. The combined action of hormones and milk factor is therefore able to raise very much the cancer rate of a strain in which normally the cancer rate is as low as it is in strain C57.

Furthermore, the genetic constitution appears to vary in a graded quantitative manner in different strains, in accordance with the observations on which we have already reported. In this way we would be inclined also to interpret certain experiments of Andervont, in which he found that the cancer rate of the father strain helped to determine the cancer rate of the hybrids. In accordance with these differences in the genetic constitution, the effect of the milk factors varies in different strains. This is evidently the reason why in non-breeding mice it is so much easier to lower the cancer rate in mice belonging to high cancer rate strains by withholding the milk factor, than to increase it in mice belonging to low cancer rate strains by supplying this factor through foster-nursing by mothers from high cancer rate strains. Without the appropriate genetic constitution, the milk factor is evidently ineffective, or only very slightly effective; but if the genetic constitution is favorable for the development of cancer, the milk factor has a chance to produce breast cancer, provided the third factor, the stimulation by hormones, is also active. Without the coöperation of milk factor and hormones, the otherwise suitable genetic constitution is unable to produce mammary gland carcinoma. However, this requirement, as far as the milk factor is concerned, seems to obtain only in the case of mammary gland carcinoma of the mouse, and not in carcinoma of the lung; nor has it as yet been determined in other types of cancer. However, in the case of leukemia MacDowell has shown that in hybrids between strains with a high and with a low incidence of leukemia, the influence of the mother strain preponderates, and according to Furth and Cole, an influence favoring the development of leukemia is transmitted through the milk of high leukemia strains; but this influence of the milk factor seems to be much weaker in leukemia than in the mammary gland carcinoma and it seems to be transmitted only to the F_1 generation of hybrids and not to successive generations of these hybrids.

The genetic factors, therefore, are of great importance in the development of mammary gland carcinoma in mice, and great differences exist in the cancer-determining constitution in different strains. Moreover, there seems to be a definite connection between these differences in the genetic constitution and the amount of milk factor a certain strain possesses. Strong indications exist that strains with a marked genetic tendency to the growth of mammary gland carcinoma possess a large amount of milk factor, and that strains with a low genetic breast cancer tendency possess only a slight amount. Thus it seems, as already stated, that strain C57, in which the genetic constitution is unfavorable to the development of mammary gland carcinoma, possesses only a very slight amount of the milk factor, or none; in strain CBA, likewise, the genetic constitution is relatively unfavorable to the formation of breast cancer, but it is less unfavorable than in strain C57; correspondingly, the amount of milk factor present seems to be somewhat greater. Data published by Andervont seem to indicate that in strain C the genetic constitution is somewhat more suitable for the development of breast cancer than in strain C57, and that, correspondingly, the milk factor is here more effective; but whether it is present in this strain in a greater amount than in strain C57 is apparently not certain, although this is possible. In the high tumor rate strains A, C3H and D, the milk factor seems to be present in larger

quantities. While this parallelism between a suitable genetic constitution and the presence of the milk factor has not yet been established in every case, the data already on hand strongly suggest such a connection.

This parallelism is a very interesting condition and it raises the question as to the origin and nature of the milk factor, and as to whether it may not be an agent produced in the mice themselves. Such an interpretation is perhaps suggested also by the statement of Bittner, if the writer understands him correctly, that if mice belonging to a high tumor rate strain have been nursed by mice belonging to a low tumor rate strain, the offspring of these mice may regain the milk factor in the course of continued propagation by inbreeding. That the milk factor probably originates in the mouse itself is further indicated by the parallelism which exists, at least in a certain degree, between the genetic constitution of an inbred strain and the amount of milk factor possessed by the female mice of this strain; otherwise we would have to assume that the affinity of an extraneous virus to various strains of mice is regulated by the degree of their genetic tendency to develop mammary gland carcinoma, an assumption which does not appear likely. However, it would be necessary to assume that the milk factor multiplies in the strains which have a high tumor rate, but that it does not multiply in strains with a very low tumor rate. If this were not so, it should be easy to transform a strain with a very low tumor rate and possessing only a very small amount of milk factor, or none, into a strain which retains its low genetic tendency to mammary gland carcinoma but possessing a large amount of milk factor. All findings published so far make such a change very improbable.

There is, however, an observation made by Bittner which it seems difficult to reconcile with this conclusion; he found that if high tumor rate strain A mice are foster-nursed by very low tumor rate C57 mice, the tumor incidence of these A mice, in accordance with expectations, is very low; however, some of these mice may develop tumors. If this latter group of mice, possessing a greater incidence of cancer, are bred among themselves, the cancer rate in the offspring diminishes from generation to generation, until in the end it becomes very low. This is contrary to the result which should have been expected if these A mice would themselves have produced the milk factor and transmitted it to their offspring; but this did not take place. A possible explanation of this condition may be that strain A mice have a high cancer rate only if they are allowed to breed and that virgin A mice have a low breast carcinoma rate. Their genetic constitution is therefore such that it needs to be supplemented by strong hormonal stimuli, which are provided by pregnancy and lactation, and that the amounts of ovarian hormone active in virgin strain A mice is unable to cause the cancerous transformation of the mammary gland in a large number of individuals. In addition there is the possibility that in strain A, also, the milk factor as a rule is produced in large amounts only in breeding mice. If in some exceptional virgin A mice enough milk factor was present to allow the development of mammary gland tumors, it is quite likely that this condition might not be transmitted to their offspring. It might perhaps be of interest to repeat this experiment with mice belonging to strain C3H, in which also virgin mice have a relatively high tumor rate.

There is also an observation of Murray and Little which seems to be opposed to the assumption that the mice produce the milk factor themselves. They found that if hybrids $(C57 \text{ } \delta \times D \text{ } \delta)F_1$ or $(D \text{ } \delta \times C57 \text{ } \delta)F_1$ are backcrossed to their parent strains, $C57 \text{ } \delta$, $D \text{ } \delta$, or $D \text{ } \delta$, in the first backcross generation the development of breast cancer is determined by the milk factor rather than by the genetic constitution. If the genetic constitution of strain D is designated by the symbol CCCC and the genetic constitution of C57 by cccc, and the presence of the milk factor by E and its absence by e, then they found in the first backcross generation the following carcinoma rates: CCCce = 2.40%; CCCcE = 35.7%; Cccce = 0.41%; CcccE = 34%. The

mammary gland carcinoma incidence of strain D is 80%, while that of strain C57 is very low. From these experiments they concluded that it is almost exclusively the milk factor which in these cases determines the breast cancer incidence. However, it seems more probable that the cancer incidence here also was determined by both the genetic constitution and the milk factor. We have to assume that the presence of C in CcccE is sufficient to allow for a cancer rate of 34%, although it does not make possible a cancer rate of 80%, which requires the genetic constitution CCCC.

If two of these backcrosses were continued for eight consecutive generations, approximately the following constitutions were obtained: (1) CCCCe and (2) ccccE; both of these have a low tumor incidence. Murray and Little concluded therefore that after eight backcrossings, the effect of the genetic constitution, as well as of the milk factor, was lost. But these results might be interpreted also as indicating that both milk factor and a favorable genetic constitution are prerequisites for a high tumor rate. In mice with the constitution CCCCe, which is genetically very favorable, the tumor rate is low because the milk factor is lacking; in mice with the constitution ccccE, in which the milk factor is present, the incidence is low because the genetic constitution is very deficient. It would be of interest to test the cancer rate of the eighth backcross generation, which possesses the constitution CCCCE; here the tumor rate incidence should be relatively high if the interpretation just given is correct. While there is thus some evidence in favor of the view that the milk factor is produced by the mice themselves, and in the largest quantity by those belonging to high tumor rate strains, the possibility that it is an extraneous, virus-like material cannot as yet be excluded.

The milk factor has been designated by Little, Murray, and Bittner as the extra-chromosomal factor in contradistinction to the genetic factors localized in the chromosomes. However, the hormone actions which are necessary for the production of mammary gland cancer may in a similar way be considered as extrachromosomal; both milk factor and hormones can be transmitted to the organism from the outside. Yet, the genetic constitution of an animal, among other factors, is responsible for the development of endocrine organs and therefore also for the production of hormones that lead to the so-called spontaneous development of mammary gland carcinoma; likewise, observations already mentioned suggest very strongly the possibility that the production of the milk-producing factor may also, directly or indirectly, depend upon chromosomal factors, as indicated by the mode of distribution of the milk factor among different types of strains. However, there is a significant difference between hormones and milk factor, insofar as the former are secreted in about the same quantities in the various strains of mice, while the amounts of the milk factor present differ very much in these strains; the genetic constitution of the latter is therefore more important in the case of the milk factor than in the case of the hormones.

Bittner first suggested that the milk factor was a hormone-like substance; however, the long-continued effect, extending over many months, of relatively small amounts of this substance made this interpretation improbable and suggested instead a complex, presumably colloidal, constitution of this factor. We expressed therefore, a number of years ago, the opinion that it might be a virus-like substance, without implying thereby that it needed to be a living organism. In subsequent investigations Bittner also adopted this view, and the recent results of several investigations, by investigators who used the ultra-centrifuge in determining the molecular size of the milk factor, led to the conclusion that it is a large molecular substance, not present in the cream partition of the milk. It passes through a Seitz filter and can be obtained from milk as well as from extracts of glycerin-treated tissues, and it is not inactivated by desiccation. The size of the active particles is less than that of some of the larger known viruses, as, for instance, vaccinia virus (Visser, Green and Bittner; Bryan, Kahler, Shimkin and Andervont). The recent work of Fekete and Little indicate that not only through the milk can a cancerigenic effect be transmitted

to mice, but that such an effect may perhaps also be transmitted to the embryo or fetus by way of the uterus. However, these experiments do not appear to be quite decisive and further investigations should determine definitely whether such an effect actually exists.

While these observations concerning the milk factor have been made in recent years, our knowledge concerning the significance of hormones in the origin of cancer has also been extended during this time. Thus we have found that the activity of the ovarian hormones may be much increased by transplantation of anterior hypophysis from mice belonging to the same inbred strain; these transplants, as a rule, remain alive during the lifetime of the host. This effect has been especially noted in virgin mice of strain A, which normally have a low rate of mammary gland carcinoma. Transplantation of the pituitary is ineffective in strain C57, in which the obstacles to the extensive growth of the mammary gland are very great; it is also ineffective in males, where ovaries are lacking.

Cramer and Horning have observed that contrary to the action of pituitary transplants, certain extracts of the anterior hypophysis may inhibit the development of carcinoma of the mammary gland which takes place under the influence of ovarian hormones; they attribute this effect to the thyrotropic hormone which is produced in the anterior pituitary. However, it seems to us possible that it is due rather to a constituent of the pituitary, which has an injurious influence on the ovarian follicles and promotes their atresia. Also, testosterone may counteract the effect of estrogen, at least in the case of benign tumors of the mammary gland in the rat (Heiman). There exists, then, a double kind of hormone action on the development of mammary gland carcinoma, namely (1) a direct action, and (2) an indirect action which affects the primary endocrine organs and the hormones given off by the latter.

Following the observation of Spiegel that adrenal cortical tumors may appear in old male guinea pigs which had been castrated at an early age, and that there developed in these animals also masculinizing effects, Woolley, Little and Fekete noted that if in mice belonging to high tumor rate strains the ovaries are extirpated soon after birth, nodular hyperplasia of the adrenal cortex develops in a number of animals, and vagina, uterus and mammary gland are stimulated; even mammary gland tumors develop, evidently as the result of the adrenal hypertrophy, which presumably produces estrogenic hormones. In low breast tumor rate strains, these effects of early ovariectomy were not observed. Of interest are also the experiments of Geschickter, who produced mammary gland carcinoma in rats under the influence of estrogenic hormones, probably in strains hereditarily predisposed to this transformation, as well as the experiments of Nelson, Moricard and Cauchoux, and of Lipschütz, who produced fibromyomata in the uterus of the guinea pig. Lipschütz found such tumors even in organs adjoining the uterus. It is known that estrogen may exert certain effects also in the male organism; correspondingly, Hooker, Gardner and Pfeiffer observed the development of interstitial gland tumors in the testicle of mice injected with estrogen. These tumors have, however, not yet reached the stage of fully developed cancer, as indicated by the fact that as in the case of some benign tumors of the mammary gland, their transplantation succeeds only if the hormone action, to which they owe their origin, continues in the new host. There are some observations which seem to indicate that in cancer of the male breast in man, administration of testosterone propionate favors the formation of osseous metastases and that orchidectomy may inhibit the growth of the mammary gland tumor as well as of the bony metastases (Farrar and Adair). Previous to these investigations, Huggins and his associates had observed a favorable effect of orchidectomy and of administration of the estrogenic stilbestrol on carcinoma of the prostate and on bony metastases of this tumor; concomitantly, the acid serum phosphatase decreased in amount. But no complete regression of these tumors occurred. On the other hand, testosterone seems to aggravate these conditions. Also, Schenken and

Burns noted regressive changes in prostatic carcinoma after administration of stilboestrol. There are some indications that in the experimental production of teratomas in the testis of birds, which, according to Michalowsky, can be accomplished by injection of zinc salts into this organ, gonadotropic hormones may play a role (Falin); a similar effect was attributed to these hormones by Champy and Lavedan in the development of seminomas, which may follow partial extirpation of the testicle in fowl. It is very probable that future investigations will add other examples in which hormones are or may be significant in the origin of cancer, and, in general, wherever hormones stimulate or participate in the stimulation of growth processes of certain tissues or organs, they may play a role also in the development of cancer of such tissues and organs. But as we have seen, it is essentially the stimulating factors in interaction with genetic factors which determine the transformation of normal into cancerous tissues, with the additional effect of the milk factor in certain instances.

So far, we have referred mainly to the differences in the genetic constitution which exist between different inbred strains of mice. However, genetic differences exist also between different species. Thus in mice, carcinoma of the mammary gland is the preponderating tumor, whereas in the rat there is apparently a much greater tendency to the development of sarcoma. The tumors which develop in the mammary gland in this latter species are largely benign tumors, in which both glandular and connective tissue elements participate. In the guinea pig, spontaneous tumors seem to be much less frequent than in the mouse or rat, this difference being essentially due to genetic conditions.

The genetic constitution determines the kind of tissues which respond readily to certain growth-producing stimuli and it determines also the mode of growth-progression in response to long-continued stimulation. To some extent, genetic factors play, here, a rôle similar to that seen in the embryonic development of individual tissues and organs. The genetic factors which act on the different organs and tissues are the same in a given individual; but notwithstanding this fact, these genes make possible the specific and distinct structure and function of these various organs and tissues constituting the organism. In the same way, the hereditary tendency to the development of cancer is specific and distinct for all organs and tissues in an individual, strain and species, notwithstanding the identity of the gene sets acting on these various organs and tissues. But whereas in the building up of the organism these inner factors—genetic factors in combination with cytoplasm and formative contact substances—essentially determine the development of the organism and its parts, in the development of cancer there is required in addition the coöperation of special stimulating factors of an endogenous or exogenous nature.

(b) **The Stimulating Factors.** Physicians and pathologists have known for a long time that chronic irritations of various kinds, chemical as well as mechanical, and also those caused by radiation and metazoic parasites, may in the end lead to the development of cancer in man. The common factor underlying these irritations is long-continued, growth stimulation of the tissues which are exposed to these injurious conditions. In the preceding account we have already described one type of stimulating factors in their interaction with hereditary factors, namely, hormones. We shall now continue the analysis of hormone action and then discuss in succession the various other types of stimulating factors active in the production of cancer and the mode of their action.

(1) *The action of hormones.* In regard to the mode of action of hormones in the production of cancer, a comparison between the rôle they play in the mammary gland, and in vagina and cervix, is of interest. Hofbauer attempted to produce abnormal proliferation in the cervix of the guinea pig by administration of anterior pituitary substance. Overholser and Edgar Allen elicited precancerous prolifera-

tions in the cervix of a monkey by injections of estrogen. In mice, precancerous lesions in the cervix have been produced by us, by Lacassagne, and by Gardner, Allen, Smith and Strong, and we as well as the last named investigators induced also real cancer growth in these organs. Allen and Overholser, in order to effect an abnormal growth in the cervix, combined administration of estrogen with incisions made into this organ. However, such incisions merely produce regenerative processes of an acute character, which in all probability are not able to intensify noticeably the action of hormones. On the other hand, we observed, in vagina as well as in cervix, indications that mechanical irritation of a long-continued, chronic nature, may make the action of hormones more effective and may determine the location in which precancerous proliferations shall take place first. In both the development of mammary gland carcinoma and of vaginal and cervical carcinoma, the cancerous growth is preceded by a preparatory growth period, the duration of which varies in accordance with the hereditary tendency to the development of cancer in these strains; and gradually, step by step, this preparatory phase passes into the precancerous and cancerous phase as the result of the hormone action. Under normal conditions, in the course of the sexual cycle the hormone affects the epithelium as a whole of a certain organ, as it does also during the preparatory growth period. Yet, one place may be in advance of another one in these proliferative processes and one area may enter first the cancerous phase; others then follow in the course of time. Both the strength and the concentration of the hormone and the strength of the genetic tendency to cancer determine the size and number of the areas that enter the precancerous and cancerous phase; in general, the stronger the hormone action and the greater the genetically determined tendency towards cancer, the larger the individual areas and the larger the number of areas that undergo the cancerous transformation and the shorter the time required, and vice versa; if both these factors are weak, then cancer may develop in a single area, while only relatively slight growth processes take place elsewhere. Gardner found, grossly, nodules consisting of proliferating mammary gland tissue more frequently in some high tumor rate strains than in a low tumor rate strain, and he believes that tumors originate from these nodules; the latter develop therefore during the preparatory growth period. Besides the hormone and hereditary factors, there are evidently other accessory factors which may exert an influence on the intensity of the preparatory growth period and the transitions of the latter into the cancerous phase. It is of interest, also, that the genetic constitutional factors differentiating the strains of mice affect differently the development of mammary gland carcinoma and of vaginal and cervical carcinoma; this is in accordance with the fact, stated above, that the genetic constitution of the whole organism in its interaction with cytoplasmic factors acts on each organ and tissue in a specific way. In some instances at least, it can be shown that this specificity in the tissue and organ constitution consists in a different degree of responsiveness to certain stimuli.

In addition to the direct stimulation by hormones and the genetic constitution, there is still another factor which plays a role in the transformation of the normal mammary gland tissue into cancerous tissue. As mentioned above, we found that the so-called spontaneous development of mammary gland carcinoma in mice, as a rule, takes place more frequently in breeding than in nonbreeding mice; but that the intensity with which this condition acts varies greatly in different strains. In some strains, the difference in the breast cancer incidence between breeding and nonbreeding mice is very great, in others less great, and we even found one strain in which nonbreeding mice seemed to develop this cancer more readily than breeding mice. Similar differences in the effects of breeding were noted in the very closely inbred strains.

As to the manner in which breeding affects the development of mammary gland carcinoma, several possibilities exist. In the first place there is, during pregnancy, a

very strong action of hormones, which induces a marked though temporary growth of the mammary gland tissue. The cancerigenic effect of pregnancy may therefore really represent merely an intensified hormone action. Secondly, it is possible that during pregnancy an intensified production of the milk factor takes place, and lastly, it is possible that a combination of both of these effects occurs. The experimental evidence which exists does not yet enable us to decide which of these possible interpretations is the correct one.

Experiments by ourselves and Suntzeff have shown that a stimulation of the mammary gland by large amounts of estrogen during the later stages of pregnancy does not tend to lead to a direct transformation of this organ into carcinoma, although the mammary gland proliferates very strongly during pregnancy, nor does the great increase in the number of cells on which estrogen now is able to act make more easy a rapid transformation of these cells into cancer.

However, in accordance with what has been established as to the influence of long-continued stimulation of mammary gland tissue by hormones, it may perhaps be assumed that during pregnancy, as the result of repeated proliferation of the mammary gland tissue due to the strong hormone action, these cells, to a certain extent, become sensitized to the subsequent action of hormones, so that they respond to the latter more readily with the production of cancer. Bagg has made use of this effect of breeding on the development of mammary gland cancer, and in mice and rats has increased the incidence of cancer by forced breeding. Such an effect was especially evident if he used hybrids between high and low breast cancer rate strains, in which hybrids the cancer rate was low but in which it may be assumed that there was still preserved the genetic potentiality to the development of cancer, which the activating effect of hormones then set into motion.

As to the mode of interaction between the various factors, genetic constitution, hormones and milk factor, in association with secondary factors such as the effect of breeding, all of these are of importance in the production of mammary gland cancer. Without the presence of the genetic factors or the milk factor, hormones are ineffective; without the presence of the milk factor, the genetic factors and hormones are ineffective. But likewise, without the action of hormones, a favorable genetic constitution and the presence of a strong milk factor are unable to produce cancer. All of these factors are necessary for the cancerous transformation of the mammary gland tissue and all are causes of mammary gland carcinoma, although each may function in its own specific way in producing this effect.

But in addition, there are indications that there exists a quantitative relation in the interaction of the three factors mentioned. As already stated, the stronger the genetic constitution in coöperation with the milk factor, the more readily can the cancerous transformation be accomplished under the influence of hormones acting as stimulating factors. But there is, likewise, some evidence that an increase in the amount of hormones acting in association with the milk factor may overcome to a certain extent an unfavorable genetic constitution. By these means, Twombly was able to produce mammary gland carcinoma in a considerable number of C57 male mice, in which the degree of genetic tendency to breast cancer is very low. This relationship between the various factors, in a general way, although presumably not in an exact quantitative manner, has been expressed by us in the equation H (hereditary or, more generally, constitutional factors) $\times S$ (stimulating factors) = C (cancer). This equation seems to apply to various kinds of cancers in various species. To cite an example from human tumors: it is possible to produce cancer through the application of light or ultraviolet rays. But under normal conditions and in normal persons this result is achieved only in a small minority of all individuals exposed to these rays and it requires a relatively long period of time in order to accomplish it. There is, however, a condition, known as xeroderma pigmentosum, in which the skin is genetically sensitized to the production of cancer under the in-

fluence of light or ultraviolet rays; in persons affected by this abnormality, the cancerous transformation occurs quite regularly.

The causes of human cancer are similar to those established experimentally in animal cancer. Human cancer also results from the quantitative interactions of genetic and stimulating factors. We must assume that in certain cases, especially in cancers which develop in early life—often on the basis of embryonal malformations—genetic factors cause a sensitization of certain tissues, which are transformed into cancer either by environmental stimulating factors or even by ordinary metabolic conditions. The large majority of cancers develop, however, during later periods of life and in these types of cancers specific stimulating factors play a more important role; they first sensitize the tissues to growth stimuli and in the end accomplish the actual cancerous transformation.

(2) *The cancerigenic action of polycyclic compounds and of some other substances.* In 1914, two Japanese investigators, Yamagiwa and Ishikawa, discovered that if the ears of rabbits are painted with tar over long periods of time, at first warts, papillomas or cutaneous horns develop, and in the end true cancer of the epidermis may be produced. There seem to be, between the papillomatous stage and the stage of irreversible cancerous growth, intermediate stages in which, in the beginning, the stimulated epidermal cells invade in an abnormal manner the underlying tissues, but in which a spontaneous regression of these invasive processes sets in after cessation of the tarring. They interpreted these observations as an experimental proof that long-continued irritation may eventuate in the production of cancer. Subsequently, Tsutsui showed that the skin of the mouse responds much more readily with the production of epidermal carcinoma to the painting with tar than that of rabbits.

It was found later that the active substances present in tar which were capable of inducing cancer under these conditions were contained in the fraction which passed into the distillate at a high temperature. These investigations suggested the search for pure substances contained in the tar which might be responsible for such a cancerigenic effect. Kennaway, with his collaborators Cook, Hieger, Burrows, Hewett and Badger, Mayneord, discovered a group of cancer-producing (cancerigenic) hydrocarbons which were derivatives of anthracene and phenanthrene, and as a result of these discoveries they have greatly aided cancer research, and afterwards, Fieser, Shear, Shields Warren and others extended these investigations. The most effective ones among these substances are, in decreasing order of their effectiveness: 9:10 dimethyl-, as well as 5, 9, 10 trimethyl- 1.2-benzanthracene, 20-methylcholanthrene, 3:4-benzpyrene, and 1:2:5:6-dibenzanthracene. These substances induce cancer when they are painted on the skin of mice or injected subcutaneously at regular intervals over long periods of time, or when they are introduced in various places into the organism in the form of pellets. They cause a cancerous transformation in the organs and in tissues on which they act.

There are, in addition, a great many substances which exert a weaker effect of the same kind, and the intensity of their effectiveness is measured by the number of individuals which, when exposed to their action, become cancerous and by the length of the latent period which precedes the appearance of cancer. However, the degree of potency varies greatly with different preparations; slight alterations, such as the introduction of radicals CH_3 , OH , or of the cyano groups, may cause great changes in the intensity of the action of these compounds; also, the position of these radicals is of importance. Usually, the introduction of oxy-radicals diminished the effectiveness of such substances and the 5, 6, 9, 10 position in the anthracene ring seems to be especially favorable for the production of active preparations. Thus the Kennaways, and subsequently Warren, found that among five dimethylantracenes, the 9, 10- compound alone produced epithelioma of the skin, and adenocarcinomas of the lung were most frequent in mice treated with this substance, but none of these preparations produced sarcoma after subcutaneous injection. However, there is no gen-

eral rule concerning the factors determining the potency of these compounds which would apply to all, and which would make it possible to foretell whether a given compound will or will not be active. At the present stage of our very rudimentary knowledge of the biochemistry of the various tissues and organs, it is to be expected that we are not yet able to interpret the mode of interaction between certain substances and specific cell constituents, which will lead first to ordinary growth processes and in the end to cancer.

There are certain other substances which probably have specific cancerigenic effects, similar to those of the typical carcinogenic hydrocarbons, although they are not anthracene or phenanthrene preparations. The most important ones among them are, perhaps, 4-amino-2:3 azotoluene and 3:dimethyl-4 amino azobenzene (butter yellow), and some related preparations, which when fed to rats or injected into mice may induce carcinoma of the liver, and these as well as certain naphthalene preparations may give rise not only to liver tumors, but may also induce papilloma formation and cancer in the urinary bladder. Here, likewise, the introduction of certain radicals into the molecule modifies their effectiveness very greatly.

There is a third miscellaneous group of many, quite dissimilar substances, which act in a much less specific way and which, after subcutaneous injection, may occasionally produce sarcoma, which is a cancer of connective tissue cells. In this group may be included estrogens, luteal hormones, preparations of liver substance used in the treatment of pernicious anemia, concentrated sugar solutions, and even buffered solutions of diluted hydrochloric acid. The action of these substances, as, for instance, estrogen, in the production of sarcoma is independent of their other more specific effects. They stimulate connective tissue cells with which they come into contact and in which they call forth regenerative growth processes. In this respect it is of interest that different types of cells or tissues seem to show a different degree of responsiveness to the action of such substances and it seems, moreover, that in general, connective tissue cells are less selective as to the kind of stimuli to which they respond than are various epithelial tissues. This is true at least as far as mouse tissues are concerned, and it suggests that an analysis of the differential physiology of tissues as distinct from those of organs may be a prerequisite to the more complete understanding of the origin of cancer.

It will also be necessary to analyze the difference in response of analogous tissues in different species. We have already referred to differences in distribution of various types of cancer in different strains of mice and in different species. There are also indications that in different human families and races the tendency to the development of cancers in the various organs and tissues differs. In evaluating the data concerning this problem, however, we have not infrequently to face the difficulty that environmental factors affecting individuals, families and races may differ in some essential respects and it is therefore not always a simple task to decide how far these differences should be attributed to genetically determined differential tissue and organ characteristics and how far to environmental factors. We have already mentioned some facts which demonstrate that different cancerigenic substances may affect organs and tissues in a specific manner. It has also been noted that a certain type of carcinogenic hydrocarbons affects the subcutaneous connective tissue more readily than the epidermis, while another type affects more readily the epidermis, and that the differential actions of these substances may differ in different species. Such differences may be due either to conditions which determine the retention, modifications or elimination of these various substances in different parts of the organism, or to specific chemical interactions between certain substances and tissues or cells. The analysis of these conditions is complicated by the fact that the results obtained may vary also with the concentrations of the substances applied. Moreover, the latent period in the action of different substances varied greatly, and apparently negative results may be due to the fact that the life span of the animals used was too

short to obtain visible results, although more subtle changes may have taken place; and lastly, the medium in which the various substances are dissolved or suspended may be of some importance (Peacock and Beck, Morton and Mider, Stowell and Cramer, Dickens and Weil-Malherbe). It has been maintained that sesame oil, which has been mentioned as a solvent for polycyclic cancerigenic substances, may, in rare cases, itself induce cancer. The term, "co-carcinogenic substances," has been used to signify the action of media which intensify the carcinogenic action of these polycyclic compounds.

(3) *The cancerigenic effects of certain metazoan parasites.* It has been observed that cancers in some organs may be caused by metazoan parasites. Thus Bilharzia (*Schistosoma*) is known to cause carcinoma of the urinary bladder; a preparatory growth period, in which papillomas may form, precedes this cancerous change. In rats and mice, Fibiger (1913, 1920) found that the nematode *Spiroptera neoplastica* (*Gongylonema neoplasticum*), which uses the cockroach as an intermediate host, may induce first papilloma and subsequently also carcinoma of the forestomach; this condition again is preceded by a preparatory growth period, in which hypertrophic changes occur in the mucosa. However, it has recently been contended by Cramer and others that in these experiments a true cancerous state has not yet been reached. On the other hand, there is no doubt that the cysticercus of *Taenia crassicolis*, which infects the liver of rats, may give rise to the development of sarcomas in the wall of the parasite-containing cysts (Bullock, Curtis and Dunning). The factor responsible for such cancerigenic effects is not known; but it seems probable that chemical substances are given off by these parasites, which exert a growth-stimulating action on the neighboring tissues.

(4) *The cancerigenic action of physical agents.* There are also physical agents which may induce cancer but which act in a less specific manner; these usually need a long preparatory period and various tissues on which they happen to act may be thus affected. Among these agents are radiations, such as Roentgen, gamma and beta rays, the latter two given off by radium; also ultraviolet rays may exert this effect. In the large majority of cases it is those parts of the epidermis, which have been exposed to these radiations, which become cancerous, but in some instances, sarcoma has developed. It is interesting that almost all human cancers due to sunlight are epidermal, because very little radiation penetrates the human skin to the dermis. On the other hand, in the albino mouse a large proportion of radiation is not absorbed by the epidermis but it penetrates to the cutis, where it causes sarcoma formation; furthermore, only wave lengths shorter than 3200 Angstroem have cancerigenic action. In guinea pigs, the injection of radium emanation has caused the appearance of periosteal sarcomas. However, the cancerigenic effect does not depend only upon the character of the radiations and their absorption by different tissues, but in addition the responsiveness of these tissues seems to vary greatly. Thus, in rats the skin responds much more readily with cancer formation to the action of ultraviolet rays than that of rabbits, although the structure of the epidermis is similar in these two species (Hueper). Furth and Butterworth, through application of large doses of Roentgen rays, produced in the ovaries of mice tumor-like new formations of the granulosa and of the germinal epithelium. Even often repeated mechanical injury of the epithelium may in the end lead to cancer formation. This has been observed to occur in the oral cavity of man, as well as in other parts of the body, and this effect is probably, in the majority of cases, due to the long-continued regenerative growth processes which follow chronic ulcerations. As to the mode of action of the radiations, it has been assumed that, primarily, this consists in setting free, or in modifying certain substances, which then cause the cancerous transformation of the tissues with which they are in contact. In the case of ultraviolet rays Roffo has attributed great significance to the action of cholesterol; however, no definite experimental proof for this hypothesis has been given.

(5) *The mode of action of cancerigenic substances.* In contrast to the estrogenic substances, the carcinogenic hydrocarbons induce cancer apparently in all, or in almost all, the cells with which they are in contact for a sufficient length of time, but, as stated, the effectiveness of different substances in this respect differs greatly. Their action may take place either locally in directly adjoining tissue, or at a distance. Some of these substances when injected subcutaneously may cause, in mice, leukemia and allied conditions (Furth and others), or tumors in the lung (Lynch), and it seems that certain strains are more prone to react in this way than others. The substances causing, primarily, carcinoma of the liver likewise are not entirely selective as to the kind of epithelium which they transform into cancerous tissue; they act on cells as unlike as liver cells and bile duct epithelium on the one hand, and surface epithelium of the bladder on the other; the effect which they exert depends probably on the length of time during which, in the process of excretion, they are in contact with different tissues. In the lung, for instance, cancer is produced by particles of carcinogenic hydrocarbons, which, after intravenous injection, are retained in the capillaries of this organ (Shimkin). The action of estrogenic substances is different; it takes place in those distant tissues to which they are physiologically and biochemically adapted. Owing to this relationship between the chemical constitution of estrogenic compounds and the receptive cells, these compounds exert both estrogenic and cancerigenic effects. Their cancerigenic function evidently depends upon their estrogenic effectiveness; the natural as well as the experimentally produced estrogens—as, for instance, stilbestrol (Lacassagne)—may differ in their chemical constitution from the typical carcinogenic hydrocarbons; still, they produce strong cancerigenic effects on secondary sex organs owing to the physiological functions which they exert.

As to the mechanism by means of which these substances bring about the transformation of normal into cancerous tissues, the following data are of importance. In the case of hormones we have seen that, step by step, they stimulate the mammary gland tissue to increased proliferation, until in the end the limit of normal growth intensity has been reached; at that point, further stimulation produces changes exceeding those seen under normal conditions and transitions into the cancerous equilibrium take place. These intensified growth processes gradually gain in momentum; they may at first be limited to a restricted area, but more and more they affect wider areas, until in the end large parts of the gland are on their way towards the cancerous transformation. The advance towards this goal takes place the more rapidly, the more the organism on which the stimuli act is genetically predisposed to this change; in other words, in proportion to the degree of genetic tendencies towards effective cancerization, the mammary gland responds more readily with growth processes to the hormonal stimuli.

This applies not only in the case of mammary gland, but it applies equally in the case of vagina and cervix; here, also, wider areas of the epithelium become stimulated, undergo hyperplasia and hypertrophy, and grow downward invasively into the underlying connective tissue and into vascular channels. However, the genetic tendencies differ in these two types of tissue and stronger stimuli are probably required in order to produce the cancerous transformation of the vaginal and cervical epithelium than that of the mammary gland tissue.

If we compare with the cancerigenic actions of these hormones those of the carcinogenic hydrocarbons, the principles seem to be similar. Differences which may exist apparently depend on the fact that while hormones are normal products of the organism and the tissues on which they act are adapted to these substances, the carcinogenic hydrocarbons are strange to the organism into which they are introduced and to its tissues. While some of the latter substances may cause the cancerous transformation of tissues with which they are kept in contact with greater intensity and rapidity than hormones do in the case of the sex organs,

they may also have secondary toxic effects on the tissues and on the organism as a whole. In the skin, these carcinogenic hydrocarbons may call forth toxic changes in the underlying stroma, and even in the epithelium. To these toxic conditions may be due certain modes of reactions in the epidermis, such as a temporary inhibition of mitotic cell division, or the greater effectiveness of fewer rather than more frequent applications of these compounds to the epidermis (Cramer). Furthermore, after administration of these carcinogenic hydrocarbons, either by means of subcutaneous injection or in the form of pellets, the sarcomatous transformation of the connective tissue cells usually is found at some distance from their strongest concentration, an occurrence which suggests that toxic effects predominate in the immediate vicinity of these substances, while at some distance a stimulation of proliferative processes takes place. The loss in weight of animals in these experiments is also in all probability due to secondary, nonspecific processes. The organism into which the hydrocarbons have been introduced uses sulfur-containing amino acids for the purpose of detoxification and the body is thus deprived of some of its necessary building stones; but it is possible that, in addition, still other injurious mechanisms, which result in harmful metabolic changes, come into play. There is no indication that the injurious action of such substances parallel their growth-stimulating effects and, as stated, it is not probable that the injurious effects are causally connected with their growth-promoting and cancerigenic action. If these compounds in solutions are painted on the skin at regular intervals there occurs, preceding the invasion of the underlying connective tissue, a period of hypertrophy and hyperplasia, with increase in the number of mitotic cell divisions in the epidermis. This increase in the number of mitoses sets in soon after the beginning of the applications of the carcinogenic hydrocarbons and it probably passes into the cancerous period. However, as Champy and Vasilin found in tarred mice, the mitotic curve is not an evenly rising one, but there are periods when the number of mitoses is lowered and, more recently, Cooper and Reller noted in mice to whose skin methylcholanthrene was applied, a marked increase of mitoses during the first 37 days, which was followed by a relative decrease in the number of dividing cells between the 37th and 65th days, and still later by another period of rapid increase in mitotic cell proliferation. The exact significance of these variations is not yet known; however, we find also in the case of some other growth stimulants, acting on normal tissues, that a positive phase of stimulation may be followed by a negative one; moreover, the level of mitoses under the influence of methylcholanthrene does not seem to return to the low level of mitotic activity, as it is characteristic of normal tissue, but it remains always elevated. As in all growing plant and animal tissues, the turgor of the cells and nuclei increases and the viscosity of the nuclei decreases after application of methylcholanthrene in tissues which are still in a stage preceding cancer; this has been shown by centrifuging these cells according to the method of Heilbrunn (Cowdry and Paletta). The same effects can be observed in the epidermal cells during the process of wound healing, but when Guyer and Claus subjected to centrifugation cells which had already become cancerous, they found an increased viscosity of cytoplasm as well as of the nuclear contents. Other effects of a marked growth stimulation, some of which may have passed already the threshold of normality, such as unequal increase in size of nucleus and cytoplasm in different cells, abnormalities in nuclear and cell division, may be hastened and intensified if strongly-acting hydrocarbons are used. In the course of the hypertrophy and hyperplasia of the epidermis which take place during wound healing, amitotic division of nuclei frequently occurs in cells which are disadvantageously situated as regards the supply of oxygen or other needed substances. Such amitotic divisions are observed likewise after application of these cancerigenic hydrocarbons. We may then conclude that, as in the case of hormone-cancer of the mammary gland and of other tissues, the production of epidermal carcinoma, caused by hydrocarbons, is preceded by a period of preparatory

growth, in which intense stimulation leads to certain structural abnormalities. A similar sequence of events is found in the small intestine (Stewart). Here, also, the growth processes of the preparatory period become abnormal at a relatively early stage. There develops an increased number of gland cells, the nuclei increase in size and become hyperchromatic. Atypical polarization of some cells is noted. These changes may accompany the invasion of the underlying tissue under the influence of active carcinogenic hydrocarbons. The probable occurrence of a preparatory growth period was likewise foreseen by the writer in the development of sarcoma following subcutaneous application of these hydrocarbons, and it was actually observed by des Ligneris. In this instance it consists in the formation of a granulation tissue in which the number of mitoses is increased. There is an increase in the number and size of cells, and abnormalities in the nucleus and cytoplasm are found. However, while under the influence of non-carcinogenic substances this granulation tissue after some time regresses, it persists and gradually changes into cancer if strong and long-continued growth stimuli are applied.

Also, in the liver the feeding of butter yellow or related substances seems to cause increased mitotic activity in the liver cells, leading at first to a nodular hyperplasia and an adenomatous proliferation, which at last changes into carcinoma. Degenerative processes, followed by cirrhosis in the liver, which may be observed in this condition, are due probably to the secondary toxic action of these substances; they do not seem to be essential in the process of cancerization and are, as a rule, not found in spontaneous hepatoma in certain strains of mice, although in spontaneous carcinoma of the liver in man the regenerative processes preceding or associated with cirrhosis may aid in or lead to the production of cancer in this organ. As we have mentioned already, cirrhosis of the liver is common if butter yellow is used as a carcinogenic substance, but occurs more readily after application of *o*-aminoazotoluene.

There is, then, very strong evidence that in all these cases a preparatory growth period precedes the development of cancer, and that this period is of significance in the cancerous transformation. We see also that if the growth-promoting stimuli affect a tissue as a whole, instead of being localized at a certain point, large areas may become changed into cancer. Such a process, however, does not need to take place everywhere at exactly the same time; more or less accidental factors may accelerate it in some places and retard it in others. We have found this tendency towards a generalized transformation into cancer in the mammary gland, as well as in vagina and cervix of mice, and it occurs also in the liver of mice. Similarly, in several types of human cancer such a condition has been noted.

These observations make it very probable that the development of cancer under the influence of various substances is due to the long stimulation of growth processes in the cells and tissues on which these substances act. A further argument in favor of this interpretation is furnished by the evidence that hormones which aid in the production of cancer, either stimulate certain tissues directly or bring about an increase in the amount of such hormones, or otherwise promote their action, while hormones which interfere with the cancerigenic effect of a hormone, interfere with the growth-stimulating effect of the latter.

This interpretation is also supported by experiments in which it was shown that appropriate concentrations of carcinogenic hydrocarbons induce in various freeliving unicellular organisms and in cultures of tissues of higher organisms, an accelerated reproduction of cells (Goldstein, Wolman, Hearne-Creech, and others). Similarly, Hammett and Reimann found that these hydrocarbons caused a stimulation of cell proliferation and development in the hydroid *Obelia geniculata*, and Owen, Weiss and Price observed that dibenzanthracene stimulated regeneration of cut segments of *Euplania dorotocephala*. Various authors (Pourbaix, Cook, Hare and Joly, Wright and Anderson), in corresponding experiments, induced changes in the carbohydrate

metabolism similar to those found in many types of cancer. However, while Spencer and Melroy observed similar stimulating effects of carcinogenic hydrocarbons on *Paramecium*, they do not believe that these effects are specific for carcinogenic compounds; also, other substances may exert such effects. It is known, of course, that many substances which are toxic if used in a certain concentration, may exert a stimulating action in weaker concentrations. But these investigators found that individual *paramecia*, when exposed continuously to methylcholanthrene for more than a year, acquired a greater resistance to the action of an unfavorable medium, to which non-adapted organisms succumbed very readily. So far, the long-continued addition of non-cancerigenic substances to the culture medium has not produced such an adaptation. These latter types of experiments would be more in accord with the fact that also in experimental cancerization the stimuli have to be applied over extended periods of time, and it is only as a result of a prolonged change in conditions that permanent alterations of the cells exposed to these stimuli take place. However, in prolonging these experiments Spencer and Melroy observed that still longer-continued, uninterrupted application of the various agents which at first may stimulate, or at least have no injurious effect, at last begin to exert an injurious effect on these organisms. This took place with bacteria and *paramecia*, as well as with worms; moreover, it was not limited to carcinogenic substances, such as methylcholanthrene, but applied also to non-carcinogenic hydrocarbons, such as phenanthrene and other agents, *e.g.*, radium. These investigators suggest that such an injurious effect might perhaps be avoided by using these substances rhythmically instead of continuously, a suggestion which is in harmony with certain conceptions concerning the origin of cancer developed some years ago by the writer, to which we shall refer later.

As we have seen, the cancerigenic response of the mammary gland to the endogenous ovarian hormones differs greatly in different strains of mice (Loeb and Lathrop), and the readiness with which the strains react to the injection of estrogenic hormones with the formation of mammary gland carcinoma varies in a corresponding way (Lacassagne; Loeb and Suntzeff). These differences are due to genetic differences in the constitution of these animals. For similar reasons, the cancerigenic response to tar and carcinogenic hydrocarbons varies in different species. But the genetic factors which determine the responsiveness of an organ to stimulation by estrogen, on the one hand, and by tar or by a carcinogenic hydrocarbon, on the other, do not seem to be the same; likewise, the genetic basis for the response of different tissues to the same stimulant (*e.g.*, methylcholanthrene) differs in different inbred strains and species. However, as a rule the animals in which cancer develops relatively quickly under the influence of these carcinogenic compounds pass more rapidly through the preparatory growth period, and if these substances are applied to the skin, warts appear more readily in these animals than in animals in which the cancerigenic reaction takes place more slowly. In general, it has been found that if a strain has a genetic tendency to the spontaneous development of a certain type of cancer, it also responds more readily to experimental stimulation with the formation of cancer of the same type. Thus, according to Lynch, those strains of mice in which there is a greater tendency to the spontaneous development of pulmonary carcinoma, react also more readily to the application of tar with the production of this tumor. Indications that the same condition holds good also in other tumors have been obtained more recently by Strong in various substrains of his mixed NH strain. It appears that treatment with a carcinogenic compound called forth, in each substrain, the development of a type of tumor to which it is genetically predisposed, and which, under favorable conditions, would therefore have a tendency to develop spontaneously. Similarly, Engelbreth-Holm noted that by application of 9, 10, dimethyl-1, 2 benzantracene, leukemia could be more readily induced in those strains of mice in which spontaneous leukemia was a frequent occurrence. These findings agree

with what has been established in the case of mammary gland carcinoma. Here, also, hormones are most effective in producing this type of tumor in strains of mice in which it most readily develops spontaneously, that is, under the influence of hormones given off in the course of the normal function of the sex glands. This takes place in strains which have a genetic constitution favoring this mode of reaction of the mammary gland. In all these respects there is, therefore, a complete parallelism between the action of hormones and that of tar and the carcinogenic compounds; both of these types of cancerigenic substances coöperate in a similar manner with specific inherited factors in the production of cancer. This similarity is also noted in the effect of the time factor on the production of cancer, if ovarian hormones and hydrocarbons are compared. In the case of ovarian hormones, it follows from our earlier experiments that mammary gland carcinoma appears the more frequently and the more rapidly, the longer the time was during which the ovarian hormones have acted. In the same way, Burns and Schenken found a corresponding relation between the length of time during which estrogen was injected into mice and the frequency with which mammary gland carcinoma developed. In the case of carcinogenic hydrocarbons, Andervont and Shear noted that the percentage of sarcomas which formed after subcutaneous introduction of pellets of methylcholanthrene was the greater the longer the pellets had had a chance to act on the connective tissue.

In various strains of mice it can be shown that very young animals respond much more readily with mammary gland carcinoma to the administration of estrogenic hormones than do somewhat older animals, according to some as yet unpublished experiments of Loeb and Sontzeff, as well as of Burns. A similar observation has been made in the induction of leukosis by means of carcinogenic compounds (Morton and Mider; Furth and Barnes). The greater responsiveness of young organisms to cancerigenic stimuli may perhaps be merely an example of the greater intensity of growth processes in general in the various organs and tissues of higher organisms in early life, and of the gradual decrease of this activity with advancing age.

We have referred already to the fact that the development of mammary gland carcinoma is initiated by a substance which is produced in the normal organism in the course of the normal function of the female sex organs with the coöperation of the proper genetic constitution and the so-called milk factor. Subsequently, when it was found that, similarly to tar, various polycyclic hydrocarbons could induce cancer in different organs, numerous attempts were made to prove that these substances may cause also spontaneous cancers and that they may therefore appear spontaneously in the body and may here exert a function leading to abnormal growth processes. If it could be proved that within the organism carcinogenic hydrocarbons may develop, under certain conditions, from normal metabolic products, the conclusion might be justified that they could in some instances be the hidden cause of spontaneous cancer. Such a possibility suggested itself in view of the close chemical relationship between bile acids and cholesterol on the one hand, and these carcinogenic compounds on the other. Moreover, it has been possible *in vitro* to prepare methylcholanthrene from desoxycholic acid, a constituent of bile. However, there is no indication that a similar process occurs in the organism. Desoxycholic acid itself does not seem to be cancerigenic, although some investigators have reported the production of sarcoma in some rats and mice after subcutaneous injection of this substance; but in this connection the fact must be recalled that the sarcomatous transformation of the fibroblasts, following subcutaneous injection, may be caused by substances with very diverse chemical constitutions, and the experiments with desoxycholic acid cannot, therefore, be used as a proof that these hydrocarbons may induce spontaneous carcinoma formation in various organs.

Another indirect method to demonstrate the significance of these substances in the origin of spontaneous tumors has been used by Shabad and various other investigators. Shabad and his collaborators, and subsequently Hieger, des Ligneris,

and Steiner, could show that extracts of human liver and lung, made with benzene or with similar lipoid dissolving media, if painted on the skin of mice or injected subcutaneously, induced in some cases the formation of squamous cell carcinoma or sarcoma in the place of application or of tumors in various distant organs. But while Shabad and his associates used benzene extracts of liver, des Ligneris, Steiner and others found only the non-saponifiable lipoid fraction effective. There is also some difference in the results obtained by different investigators as far as the location of the cancers which develop under these conditions is concerned, some observing merely a local effect, while others noted cancer formation also in distant organs. Furthermore, it was observed that the liver of persons suffering from cancer in other organs was more potent in this respect than the liver from noncancerous persons. Des Ligneris, and subsequently Hieger, found that petroleum ether extracts of liver from cancerous, and also from noncancerous Bantus, especially those of Portuguese East African descent, gave rise to the development of cancers in mice whose skin had been painted or which had received subcutaneous injections; however, only certain liver extracts were actively carcinogenic. It is known that in these, as well as in some other African races, carcinoma of the liver is a frequent type of cancer. On the whole, the number of experimental cancers thus produced in mice was relatively small and the number of substances which may produce a small number of cancers under such conditions is very great. These experiments do not, therefore, furnish a definite proof that carcinogenic substances may develop in the organism spontaneously and induce the formation of cancer.

Somewhere on the curve representing the change from the normal to the cancerous equilibrium there is a point where the mammary gland tissue becomes sensitized to growth stimuli, so that from then on the specific hormonal stimuli no longer are needed for the progression of growth, but nonspecific extraneous or the ordinary intrinsic stimuli are able to accomplish the cancerous transformation. During the process of cancerization of the mammary gland under the influence of ovarian hormones, we noticed (1919) that if the hormone action was removed at an early period of life, the appearance of mammary gland carcinoma was prevented, but if the ovarian action had extended over a somewhat longer period, its appearance was merely retarded; it could develop a long time after the factors which were responsible for the cancer formation had ceased to act. We interpreted this relationship as indicating a double action of the removal of the ovary, and, by implication, also a double action of the ovarian hormones, namely (1) one of prevention of cancer as well as the prevention of sensitization to cancer if hormones had acted only for a short time, or, on the contrary, the production of cancer at the usual rate as the direct result of the action of hormones extending over a sufficient length of time; and (2) an action of hormones of intermediate duration, which made it possible for the mammary gland to develop cancer a long time after removal of the source of the hormones. We concluded furthermore (1920) that the first tissue changes, which eventuate in the development of cancer, occur at a much earlier period of life than might have been expected, and that castration affects these primary tissue changes rather than the secondary transformation of these changed tissues into fully developed cancer. We distinguished, therefore, between two conditions: namely, (1) the preparatory tissue changes, and (2) the change of the prepared tissues into cancer. Subsequently, we interpreted the preparatory changes as constituting a sensitization comparable to that caused by the hormone of the corpus luteum, which produces a state of sensitization in the uterus. After the uterine mucosa has been sensitized by the specific action of a hormone, much less specific actions, such as incisions or other kinds of physical changes setting to work certain growth processes, lead to the production of placentomata, which may be regarded as temporary tumors. We considered, therefore, the mammary gland as being sensitized primarily by genetic factors, but a secondary, similar preparatory or sensitizing action is accom-

plished by the ovarian hormones, in particular, by estrogen, in such a way that subsequently stimuli of a nonspecific nature, namely, some stimuli acting on the tissues during ordinary life processes, were able to induce cancer formation. It may then be stated that castration at an intermediate or relatively late period prevents a direct production of cancer but does not prevent sensitization, which leads to a later formation of cancer under the influence of nonspecific stimuli.

Through the work of a number of investigators it was then shown that the same condition exists also in cancer induced experimentally by tar and by carcinogenic hydrocarbons. Leitch observed (1922) that after tar had acted for a certain length of time, the tissues had changed in such a fashion that cancer could develop a long time after this action had ceased. He concluded that a considerable time before cancer had begun to develop, a change had occurred in the tissue exposed to the tar action, which was not visible under the microscope. Similar observations were made at about the same time by Bang. In tar cancer, induced in mice, Bang (1922) divided the time which elapsed between the first tarring and the occurrence of invasive growth into a preparatory period, which lasted for several months of the treatment, until the latter had accomplished the potentiality to the cancerous change, and a latent period which began at the end of the preparatory period and extended to the beginning of the invasive cancerous growth, and in which the application of tar was no longer needed. In this paper, the term "preparatory period" includes the entire time from the beginning of the action of the cancerigenic agents to the transformation into cancer. Subsequently it was shown that incisions in previously tarred tissue could induce cancer formation (Döderlein and Lipschütz, Deelman, des Ligneris), or that a second tarring brought out papilloma formation sooner than the first (des Ligneris), and that a third and a fourth tarring was still more effective and induced papilloma formation in places in which the first tarring had been inefficient (Rous and Kidd). Twort and Twort, des Ligneris, Rous, Kidd and MacKenzie, as well as Berenblum, noted that after a first period of tarring or application of carcinogenic hydrocarbons, the subsequent application of less specific irritants or stimulating substances, such as liquid paraffin, oleic acid, turpentine, croton resin, was able to induce the formation of papilloma, or even of cancer. Another interesting related observation was made by Burrows, Mayneord and Roberts, who found that granulomatous proliferation caused by kaolin could be converted into sarcoma by the application of Roentgen rays. We may assume that the granulomatous cells were in a sensitized state tending towards tumor formation, which was activated by other agents. It may then be concluded that cancerigenic substances and also physical factors may act in a double way: 1) they may induce cancer, and 2) there is associated with and preceding this process one of sensitization, which causes the process leading towards the production of cancer to become more and more intensified if the same cancerigenic agent continues to act, or which makes it possible for factors, which ordinarily are not cancerigenic, to exert such an effect. However, there does not need to be a marked difference in principle between the action of the specific cancerigenic factors and the others which are less so or nonspecific. The difference is probably merely a quantitative one, the latter substance requiring an action extending over a much longer time in order to accomplish what a more specific substance can accomplish in a shorter time.

It follows from the experiments of Rous, Kidd and Friedewald that warts and carcinomatoid downgrowths caused by tar or methylcholanthrene in the rabbit's skin behave like sensitized non-papillomatous skin, or like mammary gland tissue sensitized by ovarian hormones in the mouse. The sensitization has occurred probably at some time previous to the development of these new formations. Of great interest is the marked difference which they find in the behavior of these papillomas in different rabbits. In some, the sensitization is quite evident; after cessation of tarring, the warts continue to grow, and, in rare cases, to become cancerous. In other in-

stances, continued tarring is required in order to maintain them, and without it they would regress; in still others, they regress even if tarring is continued. But although the warts or precancerous downgrowths (carcinomatoids) have regressed and the epidermis has apparently returned to about the normal state, these cells still remain sensitized and can be re-awakened to abnormal growth by the use of various activators; even cells that formerly had not been a part of the warts will now show sensitization and develop into warty outgrowths, presumably because they had previously been affected to a certain degree by the tar or carcinogenic hydrocarbons, although perhaps not with the same intensity as some of the neighboring cells.

The great variation which different strains of individuals manifest in their reactions to these stimulating cancerigenic factors corresponds to the great difference in the reactivity of the mammary gland to endogenous or extraneous estrogenic hormones which has been established in different strains of mice. Both are due largely to genetic differences in the constitution of these strains or individuals. This constitution may represent the primary and predetermined type of sensitization of the tissues, a sensitization of the first order; as we have seen, it determines the intensity of stimulation which is needed to induce a response of a certain magnitude, in accordance with the relation expressed in the equation $H \times S = C$. In curves representing the response of the tissue to various kinds or various intensities of stimulation, this genetic sensitization could be expressed as the degree of elevation of the starting point of the curve above the level of the baseline. The curve of growth response of the tissue could then be represented either as a straight line which turns sharply upwards at the point of sensitization, in case the latter process consisted in a single abrupt change. On the other hand, the possibility exists that the process of sensitization is not a single change, but that it consists of a succession of sensitizations in which the individual steps may be very small. In this case the response of the tissues to new stimulation would become, step by step, more intense and the curve would rise gradually upwards. There are certain indications which favor the second interpretation. If we follow the development of mammary gland carcinoma under the influence of estrogen, it seems that the progress of tissue proliferation is at first very slow and gradually becomes more and more intense. Other observations, however, merely make possible the conclusion that during the preparatory period the growth momentum of the affected tissues gradually increases, until at last the cancerous state is reached. Thus, with the continued administration of estrogen the incidence of mammary gland carcinoma increases step by step with the increasing length of time during which ovarian hormones have exerted their growth stimulation. To a similar conclusion point the observations of Andervont and Shear concerning the effect of methylcholanthrene; here also, the incidence of cancer increased with the increasing length of time during which this substance acted. In the same way, the benign formation, such as papilloma and adenoma which may develop preceding the formation of cancer, may be interpreted as intermediate steps towards cancerization. We may then conceive of the action of the stimulating factors as increasing, step by step, the growth momentum of the tissue on which they act, until in the end it has reached such an intensity that from this point on even weaker stimulations are able to carry the growth to the cancerous stage. It seems probable that different quantities of an autocatalytic growth substance correspond to the different intensities of the growth momentum, and it seems, moreover, probable that this process of gain in growth momentum continues after the point has been reached when nonspecific growth factors are able to complete the cancerous transformation of the sensitized tissue. In accordance with this interpretation, we found in our earlier experiments indications that with the increasing intensity of the hormone action, the time necessary for the appearance of cancerous growth is shortened; and other experiments, to which we shall refer, agree with this conclusion. We must further assume that in different individuals belonging to the same inbred

strain, either different intensities of growth momentum are necessary to carry the tissue into the cancerous phase, or that the growth momentum is the same in all individuals, but that the amount of stimulation needed to achieve this critical growth momentum and to maintain it varies in different individuals. This question, as well as the shape of the growth curve of the stimulated tissues during the preparatory period are problems which future investigations must solve. In accordance with this assumption of a step-by-step process in the degree of sensitization is also the observation of Rous and Kidd that a third and a fourth tarring of the skin accelerates the sequence of tissue responses, ultimately leading to cancer, more than a second tarring.

There are, furthermore, indications that even the process of cancerization consists of a series of steady changes, rather than of a single sudden change which is not followed by further progress. Accordingly, we observed that in many cases in the course of the first transplantations of a tumor the growth intensity increases. These gradations may be taken to represent different intensities of cancerization. Similarly, metastases of human cancer may grow more actively than the original tumor. Mechanical stimulation may likewise exert a stimulation on tumor cells. In our early experiments we noted, as already stated, that a cancer which, as a result of unfavorable conditions had begun to grow slowly, may be made to grow more actively under the influence of mechanical stimulation, and in the course of time, following repeated transplantations, which also act as stimulating factors, may assume a more rapid growth. In the same sense may be interpreted the findings of Rous and his collaborators that certain stimuli, in particular those exerted by papilloma virus, cause a more intense and varied cancerous response in the skin of the rabbit than does tar. On former occasions we have interpreted in this way, also, the fact that the stage of irreversible cancerous growth is preceded by a series of conditions in which at first there exists still the chance of regression, but apparently to a different degree in different instances. Of interest in this connection are also the experiments of Emmart, who recognized different stages in the process of cancerization of the liver induced in rats by feeding *o*-aminoazotoluene. In the tumor phase designated as hepatoma, metastases may occur; the structure of the tissue differs from that of normal liver tissue and there is increased cell proliferation; but this may be followed by a more advanced process of cancerization, in which the structural variations between the different tumor cells become pronounced, the growth intensity greater, and deviations from the normal growth more marked; also, neighboring areas may be invaded. The increase in growth energy in the latter phase is also indicated by a greater ability to survive in tissue culture, as compared to that shown by the hepatoma phase. We would then have to conceive of the process of sensitization and cancerization as a continuous series of short, progressive, step-by-step changes, in which, however, a discontinuous alteration takes place when a certain threshold of stimulation has been reached; at this point the change becomes irreversible; this readiness with which the threshold point is reached would vary in proportion to the primary genetic sensitization of the tissues, and, perhaps, also in proportion to certain other non-genetic factors. That such sensitizations of tissues exist also in the human species is indicated by the experience that certain industrial cancers may occur many years after a person has been removed from the original cancer-inducing environment. Furthermore, in conditions such as xeroderma pigmentosum there exists a sensitized state of certain parts of the skin; if these are exposed to the rays of the sun, cancer may develop.

Under normal circumstances, a stimulation of a tissue is followed by a reaction which can be represented by a curve which rises in a first period and then descends again to the baseline. It differs therefore from the curve representing the process of sensitization and cancerization. Similar also is the curve seen in certain rabbits in which tarring causes only a temporary papilloma formation and is followed by an apparent return to the normal state, according to the observations of Yamagiwa and

Ishikawa and of subsequent investigators. As an intermediate condition, we found in strains of mice in which the mammary gland is resistant to the action of estrogenic hormones, that the stimulation as a rule progresses so slowly that the point of cancerization is reached not at all, or only in exceptional individuals. It is possible to interpret these differences to the readiness of analogous tissues to react to various long-continued stimuli, which is noted in various species or strains of animals, as due at least in part to differences in the degree of the sensitization of the first order, which depends upon the genetic constitution of an organ or tissue in a given strain or species. Thus mice, rats, guinea pigs, rabbits and dogs differ in the readiness with which their mammary gland responds to hormonal stimulation. Similarly, rabbits and mice differ very greatly in the response of their skin to stimulation by tar, and again, some strains of mice likewise show corresponding differences.

We may here discuss briefly some further data concerning the relations of the process of sensitization to the preparatory growth period which precedes the process of cancer formation, and some of the characteristic features of the preparatory growth period. The process of sensitization takes place during this period and it is the result of the growth processes occurring in the earlier phases of the preparatory period. The more intense the growth during this preparatory phase, the more quickly it passes into the cancerous stage; this has been found in hormonal cancer and it seems equally true of cancer of the rabbit skin caused by the Shope papilloma virus, where Rous, Beard and Kidd observed that the cancer appears early in cases in which the papillomas proliferate very vigorously. Rapidity of transformation into cancer depends upon genetic constitutional factors in the mammary glands of mice as well as on the strength and efficiency of the stimulating factors, and there are indications that genetic factors may play a role also in the tar cancer of mice and rabbits. In cancer induced by hormone stimulation the preparatory period represents a continuous series of progressive growth changes. However, while in cancer of the mammary gland caused by the action of endogenous estrogenic hormone there is, in general, a relation between the frequency of mammary gland carcinoma and the rapidity of preparatory growth, in addition, peculiarities in the character of the different phases of the growth curve leading to cancer formation may distinguish various strains of mice. Likewise, the carcinogenic hydrocarbons, tar and papilloma virus may differ in the manner in which they affect different phases of the growth curve of the epidermal cells. Thus, application of an efficient tar preparation seems to cause a rapid development of papillomas, but this process is followed only rarely by cancer formation, and the period of latency intervening between the papilloma and cancer development, if the latter should occur, is long. In the case of methylcholanthrene, warts do not seem to develop as rapidly as after application of tar, but the transformation of warts into cancer occurs more readily. Papilloma virus induces a rapid formation of warts, but the subsequent formation of carcinoma, if it takes place at all, is a rather slow process (Rous and collaborators).

In the case of hormone cancer, the preparatory growth period seems to be essential for the induction of cancer. In not a single instance have we observed that carcinoma of the mammary gland develops directly from resting ducts or acini, nor is it sufficient that merely a moderate mitotic proliferation occurs in these gland structures. A period must be initiated in which step-by-step, intensified growth phases follow one upon the other in succession, and apparently only in this way is the stage of cancerization ultimately reached. The function of the preparatory growth period, and in particular of the process of sensitization, is to prevent the affected tissue from returning to its initial normal resting stage at which the growth started, and to push it on to continuously intensified growth. This requirement seems to obtain, irrespective of the kind of stimulating factors which are used, whether they are hormones, carcinogenic hydrocarbons or papilloma virus. One exception to this rule is found in the production of the cancerous stage by injecting

the agent of fowl sarcoma into normal chickens. In this instance, the normal cells are changed into cancer cells in an acute way; they seem to acquire the characteristics of cancer without first passing through a series of preparatory growth processes and of corresponding tissue changes; however, it is also possible that in this case the preparatory growth process takes a very rapid course. If the first alternative should hold good, then the difference between this condition and the usual mode of initiation of the cancerous process in certain respects is similar to the difference between passive immunization through injection of antitoxin, and the process of active immunization of an organism, which enables it to produce antitoxin. However, the transfer of the agent of fowl sarcoma to other chickens does not leave the mesenchymatous cells in the new host, which become sarcomatous, otherwise unchanged; as we have mentioned already, they acquire thereby the alterations in their carbohydrate metabolism which are characteristic of the majority of cancers.

There are indications that a relation exists between the length of the preparatory growth period and the length of life of a species. Thus the preparatory growth period seems to be much longer in man than in rodents and rabbits, and such a relation between length of the preparatory growth period and duration of life of a certain species may hold good in general. However, accurate comparisons between different species, made under strictly comparable conditions, regarding this point have not yet been recorded, and conclusions are furthermore made more difficult because of the existence of differences in the cancerigenic tendency of various tissues.

It seems, then, that the mechanism of cancer formation under the influence of various stimuli is in some way connected with the occurrence of a preceding preparatory growth period, during which processes of tissue sensitization occur. These stimulating factors interact with genetically determined conditions in the tissue substrata and certain quantitative relations seem to exist between these two sets of conditions; moreover, this rule seems to apply whatever the nature of the stimuli which are active.

(c) **Virus as a Cause of Cancer.** We have seen that certain metazoic parasites may, in special instances, induce cancer formation. There was a time when the possibility that bacteria or some parasitic protozoa might be the real cause of cancer was seriously considered. In some plants, bacterium tumefaciens may produce a tumor-like formation, which in certain respects resembles cancer in higher organisms. It has also been stated by Jensen that tubercle bacilli may give origin to sarcoma. However, if this microorganism was actually involved in the development of cancer, it can only have been in an indirect manner by inducing the formation of granulation tissue, which, under the influence of unknown stimuli, changed into sarcoma. Attention was directed towards protozoa mainly because of the occurrence in certain cancers of products of cell differentiation, which resemble encysted protozoa. These interpretations as to the origin of cancerous growths in higher animals have quite generally been abandoned.

On the other hand, in recent years another concept has gained very serious consideration, namely, that all cancers are caused by viruses. This concept owes its origin primarily to the experiments of Peyton Rous. That certain virus-like substances, as well as also a typical virus, may induce cancer formation has been definitely shown by this investigator. But Rous has, in addition, suggested that all animal cancers are essentially caused by viruses, and that all the other factors that play a role in the origin of cancer are merely subsidiary factors, which act presumably by influencing the virus or by giving it a chance to function as the true cancer agent. This view is based, in the main, on certain data which we shall now briefly discuss.

As stated previously, it has been shown by Rous and his collaborators that certain fowl sarcoma are caused by agents which can be separated from the tumor cells

by various processes, the best known of which and the one most commonly employed is filtration through filters which do not permit the tumor cells to pass through its pores. There are a number of such chicken tumors caused by distinct agents, which latter differ from one another in the type of host cells to which they are adapted, as, for instance, ordinary connective tissue cells, endothelial cells, and perhaps also monocytes, and which, furthermore, exert specific morphogenic effects on certain tissues; thus, one of these agents induces cartilage and bone formation in the mesenchymatous cells, which they invade and make their habitat in which they multiply. While they are thus to a certain extent specific, by means of immune reactions it can also be shown that they are—at least some of them—more or less related to one another. Moreover, they resemble the cells in which they live in regard to the degree of species specificity which they manifest. Primarily, these agents are adapted to the life in fowl cells, but as already stated, they may become adapted also to certain tissues of pheasants and ducks; and they resemble their host cells also insofar as they adapt themselves better to different though related species, if the host organisms to which they are transferred are very young.

The typical effect of the injections of these agents into chickens consists in the rapid change of the connective tissue, or, in general, of mesenchymatous cells, into sarcoma. A preparatory growth period does not seem to be necessary for this transformation, but these agents are particularly effective if they meet mesenchymatous cells which are in the process of proliferation (Rous). It has furthermore been observed that in chickens in which, under these conditions, a sarcoma forms, there develop at an early period, immune substances in the blood, which have the power to neutralize these agents.

However, the reaction of such agents is not limited to the transformation of connective tissue cells into sarcoma, as found by Rous, and soon afterwards, by Fujinami; but as we have likewise discussed already, several years previously Ellerman had discovered that leukemia in fowl could be transferred by a cell-free filtrate to other chickens. Leukemia also may be considered as a special type of cancer, namely, one originating in the leucocyte-producing organs, the cancerous cells in this instance being peculiar insofar as they readily invade and circulate in the vascular system.

It seems, then, that cancers from which, in mammals, a filtrable agent cannot be separated, may, in birds, contain such an agent. It was therefore of interest to inquire whether cancers induced in fowl by tar also would differ from mammalian tumors of this kind by the presence of a filtrable agent in the tumor cells. Murphy and Landsteiner, who first carried out such an experiment, found this not to be the case. But more recently, Andrewes stated that after all, the existence of such an agent has been made very likely by the demonstration in the blood-serum of fowls, in which such tar cancers had been produced experimentally, of the presence of antibodies which neutralize the filtrable agent of the Rous tumor. In a similar manner, Kidd has recently observed that in papilloma of the skin of domestic rabbits, produced by the Shope papilloma virus originally obtained from warts of Western cottontail rabbits, the presence of a virus can be shown in an indirect way by the demonstration of neutralizing antibodies in the blood-serum, although the virus cannot be demonstrated directly in the extract of the papilloma itself, in contrast to the extract of the papilloma of cottontail rabbits, in which the existence of the virus can be proven by its ability to produce papilloma in other rabbits. Analogous experiments suggest the presence of a virus also in the Brown-Pearce tumor of the rabbit (Kidd), but there seems as yet to be some doubt as to the possible interpretation of these latter results. These conclusions agree with the findings of Shope that in the papilloma of domestic rabbits a specific antigen is present, which is able to immunize normal rabbits against the papilloma virus.

As to the nature of the agents in these fowl tumors, Rous believes that they are

extraneous viruses which are adapted to certain avian cells. Murphy, on the other hand, holds that they are substances produced by the host organism itself; at first, he considered them as enzyme-like products, but more recently he compared them to organizer-like substances (mutagens) not unlike those which can be extracted from certain type-specific pneumococci. Murphy's collaborator, Claude, attempted to separate the cell constituents which are bearers of the agent or which represent the agent. As stated previously, he assumes that the agent constitutes modified mitochondria, because the chemical constitution of mitochondria and of the agent appears to be similar, and chemical alterations of the mitochondria-like tissues tend to destroy also the activity of the agent. The findings of Jobling, Schemin and Sproul seem to agree to some extent with those of Claude. The unsuccessful attempts of Furth and Kabat to separate virus-bearing cell constituents from normal ones suggest the possibility that adsorption processes may introduce a complication into experiments of this kind.

The avian sarcomas and leukosis furnish, then, one line of evidence in favor of the conclusion that virus-like substances may play a role in the development of cancer. Further evidence is presented by the findings of Rous and his collaborators that the papilloma on the skin of Western cottontail rabbits, caused by a virus discovered by Shope, can be converted into cancer. Such a transformation may take place spontaneously, but it can be hastened very much by the application of tar and carcinogenic hydrocarbons, such as methylcholanthrene, to these virus papillomas. Conversely, the application of the rabbit virus to tar papillomas may very much stimulate their growth and transform them into carcinomas. The intensity of the action of tar, methylcholanthrene and the virus differs very much and the character of the carcinomatous changes brought about by these substances is not exactly the same. Likewise, as mentioned above, the time relation as to the appearance of these warts and as to their conversion into cancer differs in the case of these three substances; furthermore, the areas in the skin affected by the Shope virus in the same animal are different from those affected by tar, and in addition, individual rabbits differ in their reactions to tar and to virus.

From these facts, Rous draws the conclusion that the increase in the effect which is observed if virus, tar, or methylcholanthrene are combined, is not due to a summation of the action of these three substances, but that the virus is the essential wart-producing and cancerigenic agent, while tar or methylcholanthrene merely intensify the effect of the virus, perhaps by modifying its chemical constitution in such a way that the virulence is increased.

However, we believe it more probable that all these substances act, in principle, in the same manner; they cause first a sensitization of the tissue by intensifying its growth momentum, then activate its further growth, and finally convert it into cancer; under some conditions, a combination of these substances may be more effective than a single substance, because the time and intensity curves of these substances differ. Of interest in this connection is the observation that continued action of a stimulating substance on a tissue or organ may gradually lead to an exhaustion or reversal of the growth effects, suggesting the inhibiting action of local, or perhaps also of generalized immune processes. We and our collaborators noted such curves in the action of iodine and of anterior pituitary extracts on the thyroid gland, and also in the action of the corpus luteum on the uterus of the guinea pig. Such a gradual diminution in the effectiveness of these substances might perhaps be prevented by the use of new growth-stimulating substances, to which the tissues are not yet accommodated.

We have already mentioned the fact that if the rabbit papilloma virus is applied to the skin of domestic rabbits and here calls forth papillomas, the virus cannot as a rule be demonstrated in the cancerous tissue which may develop subsequently, but that by means of immune reactions its presence in these tissues can be made prob-

able. As to the nature of the papilloma virus, Beard and his associates believe that it is a macromolecular nucleo-protein. It has been maintained that also the ordinary wart which develops in the human skin can be transmitted to other places of the skin by cell-free material from the warts; this would indicate that these small papillomatous tumors, too, may be caused by a virus. There are still other observations which point to the more general significance of viruses in the origin of cancer. In some amphibia, tumors have been observed, which seem to be produced by a virus. Thus the Champys found an epithelioma in *Triton alpestris*, which apparently could be transferred to other animals belonging to this species, but not to other species of *Triton*, by the water in which the bearers of this cancer had lived. They concluded that the successful transmission of this tumor was due not to the growth of the transplanted cells in the host, but to the action of a virus transferred with the cells. Lucké noticed in a Massachusetts race of *Rana pipiens* the frequent occurrence of kidney tumors, which varied in structure and activity between adenoma and metastasizing adenocarcinoma. These tumors likewise seemed to be caused by a virus, as indicated by the presence of intranuclear inclusion bodies in the cells of these new-formations and by the fact that transplantation of this tumor succeeds only in the anterior chamber of the eye, and that inoculation with this material of other frogs of the same species and race, as well as of frogs belonging to a different species or race, to other parts of the body, induces tumor formation solely in the kidney, irrespective of the place where the tissue has been implanted or injected, and that such a tumor formation occurs also if the inoculated material has previously been frozen to -80°C and powdered, a procedure which presumably kills all the tumor cells. This virus would therefore be organ-specific and at least approach species or race specificity. According to Briggs, in frog larvae transplants of this tumor may grow in various locations; but in these larvae also, the tumor inoculated elsewhere may induce multiple tumors in the kidney, which seemed to have originated through cancerous transformation of the kidney tubules and therefore were not metastases developing from inoculated cells. For this reason, Briggs considers these renal tumors as caused by a virus.

We have already discussed the significance of the so-called milk factor in the origin of mammary gland carcinoma of mice, and we shall now consider the bearing of this factor on the virus problem. The milk factor is a substance which in certain respects resembles a virus in its action and may be designated as a virus-like substance. In accordance with our previous discussion, there is at least the possibility that it originates in the mice which are bearers of the mammary gland carcinoma and that its occurrence corresponds, to a certain extent, to the degree of genetic tendency to tumor formation in this organ in various strains of mice. Its mode of action is not an acute one, comparable in this respect to the avian sarcoma agent, but on the whole it resembles rather that of the rabbit papilloma virus. However, the milk factor differs from the latter not only because of its possible origin from the tissues of the bearer, but also because it exerts, probably, a physiological function, inasmuch as there are indications that it participates in the noncancerous growth of the mammary gland ducts and presumably promotes the preparatory growth period of the mammary gland. In favor of the view that all kinds of cancer are essentially caused by viruses, two additional observations might be cited. In the course of serial transplantations of tumors in mice, sometimes as early as after the first or second transplantation, the growth of an epithelial tumor, a carcinoma, seemed to induce sarcoma formation in the adjoining connective tissue stroma. In another series of transplantations, the writer noted that at a point where a transplanted adenocarcinoma came in contact with the overlying epidermis, the latter began to grow downward into the underlying stroma and thus to assume a carcinomatous invasive growth. These observations suggest the possibility that in these cases virus-like substances were transferred from epithelial cells to neighboring connective tissue cells, or from glandular

epithelium to squamous cell epithelium, and here induced the newformation of cancerous growth. However, an objection might be raised against this interpretation. As a rule, when a virus has been shown to be active in the production of cancer, it was tissue- or organ-specific. Such a specificity would not very well be compatible with the assumption that a virus can be transferred to a different type of tissue, and would then be able to transform the latter into cancer. Instead, it may be suggested that in the instances mentioned we have to deal with the action of substances present in the cells of the primary tumor, which exert a stimulating effect on neighboring tissues. Similar contact-growth substances may be active even under normal conditions. Thus, we were able to demonstrate that epithelial tissues, as a result of processes taking place during their growth, may stimulate the proliferation of the adjoining stroma. Cancer cells may perhaps possess substances which initiate intense growth processes of an autocatalytic nature primarily in the tumor cells themselves, but which, under certain conditions, may also be transferable to adjoining tissues. On the other hand, the observations of Duran-Reynals, to which we have referred already, indicate that in the course of time a virus may undergo certain changes, which enable it to adapt itself to a strange host and, within certain limits, to induce tumor formation in tissues different from those in which it had grown originally. However, the new tissues which were invaded by virus were, on the whole, related to the original ones; a change from connective tissue to leucocytes or their progenitors being observed; but a transfer to epithelial tissues did not take place.

A second observation which likewise was made in the early period of experimental cancer investigation, which we have already noted, is the increase in growth energy which cancer cells often acquire during the first or, sometimes, the later transplantations. Such an increase in growth energy or in the intensity of certain metabolic processes, as a result of the serial transfer to other hosts, has been found also in bacteria and in viruses, but not, so far as we know, in normal cells. But then we must consider the fact that cancer cells in certain respects differ, in their mode of growth and reaction to hosts, from the normal cells from which they originated, and it is possible that they may acquire some new growth characteristics during the process of cancerization.

From all these data we may conclude that certain viruses may stimulate normal tissues in such a way that they become converted into cancerous tissue, especially under conditions in which the action of the viruses is associated with various other stimulations of a chemical or mechanical kind; and furthermore, that in birds an agent of an exogenous, or possibly of an endogenous, nature, which is responsible for the cancerous growth of certain cells, can be separated from the cancer cells and transmitted to analogous tissues of the same species or of a few other nearly related species, and here induce in the affected cells the development of cancer of the same or of a related type. The experiments which we have discussed also suggest that viruses or virus-like substances of an exogenous or endogenous nature may be present in some instances, in which their presence cannot be demonstrated in a direct manner, and lastly, they show that certain cancers may be due to a more complex system of conditions than had previously been believed. These conditions include: (1) Inherited genetic factors transmitted through the germ cells; (2) continued stimulation of certain tissues, not only by a variety of well defined physical and chemical factors but also by certain viruses; (3) a virus-like factor, which may be active in the production of cancer only in coöperation with the other factors mentioned; this virus-like substance may possibly be of an endogenous nature and may perhaps exert even some physiological function.

However, Peyton Rous and Andrewes go farther and conclude that all cancers are essentially caused by viruses and that all other factors are merely subsidiary, either modifying the virus, increasing its cancerigenic efficiency, or making the recipient tissues more responsive to the cancerigenic action of the virus. Andrewes,

in particular, has suggested that exogenous viruses may enter tissues at an early age and here lead a passive existence until certain injuries affect the host cells or some changes act directly on the viruses. In this connection it may again be stated that, as far as is known at present, the cancerigenic viruses or virus-like substances seem to be, to a large extent, organ- or tissue-specific, at least as far as their ability to induce cancerous growth is concerned, and that adaptation of the viruses to different tissues has been observed only within a relatively narrow range.

Inasmuch as all tissues which still possess the potentiality to grow may become cancerous, it would then need to be assumed, according to Andrewes, that the number of exogenous viruses which have invaded the animal organism in early life and from then on make certain organs and tissues of the latter their permanent habitat, must be considerable; indeed, a large number of different tissues and organs would have to possess their own specific viruses. Furthermore, the additional possibility must be considered that the cancers caused by different stimuli in the same organ or tissue may differ as far as the genetic factors involved are concerned. Thus it is known that estrogen produces mammary gland carcinoma readily only in mice belonging to certain strains, while in mice belonging to other strains estrogen is ineffective. However, one of the latter strains, owing to its genetic constitution, may be especially prone to respond with the formation of mammary gland carcinoma to the application of certain carcinogenic hydrocarbons. If, in each of these instances, a virus were the principal factor in the initiation of this type of cancer, the possibility might have to be taken into account that more than one virus resides in certain organs, as for instance, the mammary gland, one responding to the cancerigenic action of estrogen and another responding to the action of carcinogenic hydrocarbons. The number of viruses residing in normal tissues would then have to be still further increased.

But another interpretation also seems possible, which would limit the significance of viruses in the etiology of cancer in the following way: (a) Certain viruses may act essentially as growth stimulators for those cells or tissues to which they are adapted, resembling in this respect growth-promoting hormones, carcinogenic hydrocarbons, and various other less specific growth stimuli, which all are capable of causing the transformation of normal tissues into cancers. According to this view, each of these factors exerts its cancerigenic action in its own way, which may differ in intensity and also in certain other particulars from the mode of action of the others. Some combinations of two or even more of these stimulating factors may lead to a considerable acceleration and intensification of the effect, as compared to the effect exerted by a single one of them. (b) In one type of cancer, however, the avian sarcoma, and in avian leukemia, it has been possible to separate from the cells a growth-promoting substance, which when injected into other individuals of the same or a related species, very rapidly transfers to certain cells, as it were, passively, a very effective agent, which propagates within the cells and acts like an autocatalytic growth substance, inducing cancerigenic growth and at the same time changing some important metabolic functions of the invaded cells. (c) There exists a virus-like substance, the so-called milk factor, which acts as a partial causative agent in the cancerization of the mammary gland and which is active only in association with specific stimulating and genetic factors, all of these three conditions being of importance. It is possible that in the future there will be found still other instances in which such a partial cancerigenic virus-like substance supports other factors in producing a certain type of cancer. According to this view, in all these cases, with the exception of avian sarcoma, viruses would not be supra-ordinated but coördinated factors in this process, and some of them acting in principle not unlike many other stimulating substances. Furthermore, in this connection it is necessary to recall the fact that the nature of the viruses is not fully understood at the present time. There still remains the possibility that they represent complex macromolecular chemical compounds

rather than active microorganisms, and that they thus may be related to the autocatalytic growth substances which we have assumed to be the direct cause of cancer.

In favor of this second interpretation as to the significance of viruses, there may also be cited the fact that, as a rule, cancerization represents a step-by-step, intensified growth process, such as may be produced by hormones, by cancerigenic hydrocarbons, or by various other substances and physical conditions conferring a continuously increasing growth momentum on the tissue's substratum on which they act. In this process, the preparatory growth period is an essential component, and the stimulating agent may fail to be effective because, on account of the hereditarily determined inertia of certain tissues, the more advanced differences in this respect between different strains or individuals, depending upon their genetic constitution and upon the character of the stimulating factor. This can be readily understood if we accept the second interpretation of the character of viruses, but it would be more difficult to understand if we assumed that all cancers are induced essentially by viruses and that all the other factors mentioned are merely of subsidiary significance, which help the virus, inhabiting all the cells of a certain organ or tissue, to set the cancerous process into motion.

Moreover, the latter assumption would bring some other difficulties. If all cancers are caused essentially by specific viruses inhabiting all the cells of certain organs and tissues, what would then be the mode of action of an extrinsic virus, such as the rabbit papilloma virus, which when rubbed into the skin gives origin first to warts, and, ultimately, to cancer? There would then be two cancerigenic viruses superimposed upon each other: first, the indigenous virus of the rabbit epidermis, which is able to give origin to squamous cell carcinoma if it is spurred on to do so or in some way is transformed by tar or other carcinogenic substances into an active cancerigenic agent, and secondly, the extraneous cancerigenic virus. Does the latter act on the intrinsic virus in the same way as tar or a hormone is assumed to act? Or do these two viruses coöperate? As to the mode of action of a cancerigenic virus on the tissue substratum, is it supposed, step by step, to intensify the growth processes in the cells in which it lives? If this should be so, its action would be about the same as that which hormones as well as some other growth-promoting factors are known to exert on these cells.

In view of all these considerations, we think it more probable that, with the exception of the agents active in avian sarcomas, viruses are coöordinated as cancer-producing factors with various other specific or less specific factors; in principle, they act like hormones and the other cancerigenic agents which we have discussed, although the milk factor may perhaps affect the responsiveness of the tissues to the stimulating condition. Such a view leaves unimpaired the great interest and importance of the facts established by the study of the action of cancerigenic viruses.

(d) **Age and Cancer.** We have discussed so far the genetic factors and the stimulating factors, including viruses, in the origin of cancer. There are some additional data concerning the origin of cancer which are based primarily on clinical observation and on microscopical study of human cancer, but which can be correlated also with experiments and observations made in animals. These concern, for instance, the effect of age on the development of cancer and the origin of cancer during embryonal life which has been noted in certain types of tumors. In general, the frequency of cancer increases with increasing age; but in some organs cancer reaches a maximum frequently at an intermediate age, after which it declines again, a condition presumably due to peculiarities of the life curves of various organs and of the stimuli reaching them. There is reason for believing that the increase in the incidence of cancer with increasing age is due primarily to the fact that the sum of stimuli affecting all the tissues and organs increases with increasing age. Furthermore, certain changes which the tissues undergo with advancing age, such as hyalinization

of the stroma, may modify the response of the tissues to stimuli, impede their return to the original normal state, and cause injuries to the tissue, resulting in long-continued recurrences of regenerative growth processes. In addition, diseases which predispose to the development of certain cancers by initiating growth processes, exert their effects with increased frequency in adult life and in old age. Similar relations of age to the incidence of cancer may be observed also in animals. Thus, in mice, cancers of the mammary gland usually appear only in middle-aged or older mice; however, they develop the earlier the more favorable the genetic constitution of an individual or inbred strain to the cancerous transformation of the organ, and the greater will be, therefore, the number of individuals affected by cancer. If the genetic constitution is favorable to the production of this type of cancer and if the stimuli have been very effective, cancer may appear even in young individuals. However, as has been mentioned already, there exists, besides, certain strain or family peculiarities as to the time of appearance of mammary gland cancers.

Of special interest are certain tumors which begin to develop during embryonal life and are associated with abnormalities of embryonal tissues, and which may be of two kinds. In the first place, disturbances may occur in some organs, such as the kidney, apparently at definite stages of embryonal development, which predispose these organs to tumor formation. Kidney tumors of this type as a rule are malignant. Secondly, there is a type of embryonal cancer which resembles a whole embryo, inasmuch as a number of varieties of tissues, and even rudimentary organs of various kinds irregularly arranged, constitute this tumor; one or more of these constituents may assume cancerous growth. Such tumors occur most frequently in the ovaries and here they are due presumably to the parthenogenetic development of eggs. This interpretation is supported by the relatively fargoing, apparently spontaneous, parthenogenetic development of eggs which we have observed relatively frequently in the ovary of the guinea pig. Similar formations may originate also in some other places in the body, where, probably, aberrant germ cells have settled and developed. Chorio-epitheliomatous structures which may be found in ovary and testicle, have very likely a similar origin. However, these abnormal embryonal structures as such would not yet constitute cancers, but not infrequently it happens that secondarily one or several of the tissue constituents of these complex tumors assume cancerous growth. Regarding the factors which cause the transformation of these various embryonal tissues into cancers, no definite knowledge exists, but there can be little doubt that some growth stimuli, perhaps even of a nonspecific nature, are able to induce the cancerous transformation. Such an effect may readily be understood if we assume that these embryonal tissues behave like sensitized adult tissues, which, as we have pointed out, may readily be transformed into cancer by various nonspecific stimuli, such as occur even under ordinary conditions of life.

Thus, the variety of types of cancers which have been observed is very great and the variety of conditions under which they develop is equally great; but the principles underlying their formation seem to be similar in all instances known so far.

(e) **The Effect of Nourishment on the Development and Growth of Tumors.** The foodstuffs which an animal consumes also influence tumor growth and may therefore be included among the etiological factors already discussed. In appraising the significance of diet on tumor growth, we have to differentiate between its effects on the growth of already established tumors and on the transformation of normal into cancerous tissue. As to the former, it has been observed by a number of earlier investigators that undernourishment may interfere with the growth of tumors after transplantation into a new host. More recently, Voegtlin and his associates have found that certain amino acids, such as lysine, cystine and methionine, which are necessary for normal growth, are necessary also for the growth of mammary gland carcinoma. Bischoff and Long showed that general undernourishment, without particular deficiency in one of the specific basic food requirements, inhibited the growth

of mouse sarcoma 180. Likewise, a deficiency in panthothenic acid resulted in growth inhibition (Bischoff and Long, Morris). However, inasmuch as this substance interferes with the state of nutrition, as a whole, of the animal, it is possible that this latter factor may also be involved in the retardation of tumor growth under these conditions and that we may have to deal with complex effects.

Distinct from these investigations are experiments in which the effect of dietary factors on the origin of cancer was studied. Of special importance in this line of investigation are the experiments of Tannenbaum, who showed that the development of spontaneous mammary gland carcinoma and of pulmonary adenocarcinoma in mice, as well as the experimental production of epidermal carcinoma or subcutaneous sarcoma by the administration of carcinogenic hydrocarbons, was markedly diminished or long delayed as the result of undernutrition, without regard for the lack of any particular dietary component. These results were confirmed by Visscher. Tannenbaum, moreover, noted that the dietary deficiencies which sufficed to prevent the newformation of tumors did not need to interfere with the growth energy of tumors after they had once developed. If once the normal cells have changed in such a way that a self-perpetuating growth stimulus has developed in the cells, this stimulus may be able to overcome the impediment to further growth caused by a deficiency in foodstuffs. In accordance with the experiments mentioned, it has been shown in our laboratory that a certain parallelism exists between the development of mammary gland carcinoma in mice and the relative state of nourishment of these animals, as expressed in their weight curves. In general, it is probable that dietary deficiencies act on tissues and tumor growth by interfering with the supply of building stones which organs and tissues need during the process of growing, and also with the maintenance of the grown organism; but it is probable also that, to a certain extent, a tumor once established can draw to itself foodstuffs which under ordinary conditions would be used by the normal tissues. In addition to these direct actions, undernourishment may indirectly affect the development of mammary gland carcinoma by causing atrophic conditions in the fat tissue and an increased formation of hyaline connective tissue, in which the normal mammary gland tissue is embedded. These changes secondarily induce an atrophy and destruction of the mammary gland tissue and thus diminish the quantity of tissue substratum available for carcinoma formation.

While, therefore, undernourishment as a rule tends to inhibit or prevent cancerous growth, there are some conditions where it has the contrary effect, and when it may help to initiate cancerous growth in certain organisms, or may lead to the production of precancerous papillomas in the stomach or to leucoplakia in the mouth (Movs and Lippincott, Rhoads and associates). The changes found in these organs may be due to general undernourishment, or, more probably, to vitamin B deficiencies; the latter seem to be responsible for leucoplakia in the tongue. It appears that lack of foodstuffs in general, or of special foodstuffs which usually tend to restrict growth processes, may under certain conditions, on the contrary, cause an increase in mitotic proliferation; this has been observed by Blumenthal and the writer in the adrenal cortex of the guinea pig, where undernourishment may cause inhibition as well as intensification of growth processes, and here the conditions for these two opposite effects can be separated. It is probable that undernourishment in this organ may stimulate mitotic proliferation, by causing the removal from the cells of some substances which tend to inhibit growth.

An inhibiting effect on the growth of transplanted tumors has likewise been observed by Ball, Samuels and Schott in hypophysectomized rats. This effect is due presumably to metabolic deficiencies caused by the lack of the hypophysis; but it is possible that some other factors are also involved in this process. This result of hypophysectomy has been confirmed by several investigators, and more recently by Gardner, who found that also the spontaneous development of mammary gland carcinoma in mice may be inhibited by lack of the hypophysis. In general, these experi-

ments confirm the conclusion that all processes which tend to interfere with normal growth, may also interfere with the development of cancer, and that they exert this effect mainly by inhibiting in the tissues the preparatory growth processes which lead to the cancerous transformation.

(f) **Somatic Mutations as the Cause of Cancer.** Cancerous growth represents a change in somatic cells, which, as far as is known, is irreversible; there is no evidence that a cancerous cell can ever regain its normal state of proliferation and function. This origin from adult somatic cells applies to the large majority of all cancers, although in a limited number of cases cancerization in all probability affects the germ cells and embryonic tissues. The permanency of the changes induced in somatic cells by cancerization is similar to that caused by mutations primarily in the germ cells, but occasionally, also in somatic cells. This fact has suggested the conclusion to a number of investigators, and especially also to Tyzzer, and subsequently to Little and Strong, that somatic mutations might be the essential cause of cancer and all other participating factors would merely be subsidiary. Accordingly, it has been assumed and is still held by many investigators that long-continued stimuli acting on a somatic cell may, in the end, bring about a permanent change in chromosomes and genes, representing a mutation which is responsible for the development of cancer.

Several observations seem to support this view—thus, through application of Roentgen rays it has been possible to produce mutations in germ cells experimentally, and, correspondingly, it is known that long-continued use of these rays has induced epidermal cancer in a number of instances. Some other changes observed in the experimental study of cancer have likewise been explained on the same ground. Thus the fact, already mentioned, that very often in the course of the first transplantations of a tumor, the growth energy increases, and that accordingly the number of successful transplantations also may increase—a change which in some instances may occur in the course of later transplantations—has been attributed to somatic mutations in transplanted cancer cells. This would presuppose that in very many, perhaps in the majority, of cases, the process of transplantation induces a somatic mutation, which invariably increases the growth energy of a tumor cell in a definite way; and furthermore, that the change induced in a single cell then determines the character of the whole tumor resulting from the transplantation and that in the succeeding transplantations this process may be repeated; but that if once these mutations have occurred, no further somatic mutation of this type as a rule takes place. As pointed out in a preceding chapter, it appears much more probable that the process of transplantation acts as a stimulus, setting into motion changes corresponding to regenerative growth and thus increasing the growth energy of the tumor cells to a maximum and bringing about an intensification of the cancerous growth. In a similar manner, adherents of the mutation theory have explained the fact that if two or more mammary gland tumors originate in the same mouse, or in two mice of the same inbred strain, they may differ from each other in the readiness with which they can be transplanted into other mice, these differences being attributed to differences in the somatic mutations which give origin to the two tumors. Instead of this interpretation, it appears more probable that we have to deal in these cases merely with different intensities in the process of cancerization which these two tumors have attained, and that the farther a tumor has progressed in this direction, the greater its growth energy will be. In principle, the same process has occurred in both of these tumors, but in one of them it happened to progress more rapidly than in the other.

Somewhat related observations have been made more recently by Reinhard and his associates; a tumor originating in a mouse belonging to the cancer-rich D strain could, as is so commonly the case, at first be transplanted solely into other mice belonging to the same strain, but not into individuals of the C57 strain. However, after application of Roentgen rays to this tumor, it grew, also, in a certain proportion of C57 mice, the proportion increasing in the beginning with increasing doses of

Roentgen rays, but then, after having reached a maximum, decreasing again. This change in the transplantability of these tumors in the C57 mice was maintained in serial transplantations and it was therefore attributed to a somatic mutation which had occurred in a tumor cell exposed to the Roentgen rays. However, another explanation which would explain these observations may be suggested. As a result of the Roentgen ray treatment, the metabolism of the tumor cells was affected in such a way that the individuality differential of these cells was modified in certain respects. On account of the change brought about in the cells thus treated, they were no longer able to produce this differential substance in the same quantity as previously, or the individuality differential they produced and gave off had lost some of its specific features. As a consequence of these alterations, the strength of the reaction of a genetically different host, such as a C57 mouse, against the transplant was diminished and the tumor grew and was able to develop in a certain proportion of these otherwise unfavorable hosts; but if still larger doses of x-rays were used, also the power of resistance to injurious conditions on the part of the transplant was diminished and consequently the ability of these tumors to grow in unfavorable hosts decreased. The occurrence of a somatic mutation which would render the genetic constitution of the tumor cells more similar to that of the C57 strain, would presuppose a concurrent alteration in their genetic constitution of such a kind that their behavior after transplantation into their own strain should be altered. While apparently an experimental test of this effect has not been made, it seems probable that it would not show a diminution in the degree of transplantability of the tumor into its own strain as the result of the Roentgen ray treatment.

Similar difficulties exist also in other instances in which the transplantability of tumors has been attributed to somatic mutations. Bittner, for instance, assumes that the occurrence of mammary gland carcinoma in certain low tumor stock mice, and in some descendants of high tumor stock mice which had been foster-nursed by low tumor rate females, cannot be accounted for by the assumption that it is due to the same factors that induce the development of mammary gland carcinoma in normal high tumor rate mice. He attributes the cases of breast cancer which develop under these circumstances, to somatic mutations taking place in the mammary glands of the mice developing the tumors. However, it might also be assumed that these low tumor rate strain mice are not entirely devoid of the required genetic constitution, and that the high tumor rate strains foster-nursed by low tumor rate strain females still possess a small amount of the milk factor necessary for the occurrence of mammary gland cancer. Certain secondary factors would then make possible the occasional occurrence of a tumor in such mice. The nature of these secondary factors is unknown, but their existence must be assumed also in order to explain why the incidence of mammary gland tumors, which differs so much in different strains of mice is associated with great differences in the behavior of the individual mice belonging to these strains, and with a constancy of the percentage of tumor incidence and of the average tumor age in the strains as such.

However, aside from these difficulties, there are others of a more general kind, which make the interpretation of somatic mutations as the essential cause of cancer improbable. A somatic mutation is a relatively rare chance phenomenon, which, if it occurs at all, should occur in an isolated cell and here induce a sudden abrupt change in the conditions and reactions of this cell and its descendants. But if we study cancer development in the mammary gland, as it takes place under the influence of endogenous or exogenous estrogenic hormones, we find that this process affects whole complexes of gland cells simultaneously; it is a change which affects the structural gland units, the tubules or acini, and may affect several units at the same time or in succession, first in one area of the gland and then in another area, until in the end great parts of the gland may become cancerous, a condition which does not harmonize with the theory of somatic mutation as the cause of cancer, which presumes

a one-cell, discontinuous origin of cancer. Furthermore, the mammary gland tissue shows not an abrupt but a continuous structural change from the normal to the cancerous state, and before a definite precancerous stage has been reached, a continuous series of graded cell-changes has occurred, which leads, as we maintain, to a sensitization of these cells. All these successive alterations require a considerable time; they take place gradually, step by step, and represent a graded series of processes which depend primarily upon the sensitizing action of hereditary factors. Such a curve of changes, eventuating in the cancerous transformation, is not very well compatible with the concept of a somatic mutation as the cause of cancerous growth. It is hardly conceivable that somatic mutations should be produced in numerous mammary gland cells and in various places almost simultaneously, exactly at the time when the estrogenic stimulation, progressing steadily, has at last reached the point where the transformation into a cancerous state of growth may occur.

In principle, we find a similar condition if in vagina and cervix the epithelium undergoes precancerous or early cancerous changes at various points and at about the same time, under the influence of stimuli which act on these cells also under normal conditions; besides, the processes leading to cancerous transformation seem to be the same also in the epidermis when it is stimulated by tar or carcinogenic hydrocarbons. However, in the latter case we have to deal with abnormal extraneous substances, which may cause accessory injurious effects. Here there may occur, in association with the increased proliferative activity, certain pathological deviations from the usual modes of growths, perhaps as an indication of the great intensity of the stimulation or in consequence of toxic side-effects induced by these substances. But in this case, as well, a series of preparatory growth processes ultimately leads to the appearance of cancer. Different from these processes is the rapid production of various types of fowl sarcoma following the injection of specific agents, where it is hardly conceivable that a somatic mutation of a single cell would be induced at once by the transmission of the agent, a point which has been emphasized by Rous. None of these processes can be explained in a satisfactory manner if we assume that a somatic mutation is the cause of cancer in general.

Lastly, it may be stated that in embryonic development we have an example of a continuous series of irreversible cell-changes which are not due to mutations—germinal or somatic. The genetic constitution of the segmenting eggs, as far as known, is the same as the genetic constitution of the adult epidermal cell, gland, muscle or nerve cell. During embryonic development, a step-by-step diminution in the proliferative activity and in the movements of the various cells and tissues takes place. Associated with these changes are alterations in the chemical constitution of the developing cells and tissues, which are different in kind from those characteristic of somatic mutations and yet are permanent. During cancerigenesis, the opposite process occurs; instead of a diminution, there is a graded increase in the proliferative and motor activity of cells and again there are associated with these changes, chemical and structural modifications which, in certain respects, make the reactions of these cells similar to those of embryonal cells. Such alterations likewise are permanent. It seems, therefore, conceivable, and even probable, that also the cancerigenic cell-changes do not depend upon somatic mutations. In addition, there is no case known of an experimentally produced somatic mutation which has resulted in cancerous growth, and on the other hand, in no case has it been possible to prove that a somatic mutation was the cause of a cancer.

These data are, then, not favorable to the conclusion that somatic mutations are the essential cause of the cancerigenic processes. On the other hand, mutations which alter the constitution of germ cells may be an essential factor in the origin of cancer, insofar as such mutations determine the degree of hereditary tendency towards the development of cancer which these organs and tissues possess and their responsiveness to cancerigenic stimulations. However, in the discussions concern-

ing the cause of cancer the term "somatic mutation" has been used by some investigators, including the writer, not in the strict genetic sense, but in a less well defined way, in order to signify that irreversible changes of some kind have taken place in cells during their transformation into cancer, irrespective of the mechanism through which they have been accomplished. However, this use of the term somatic mutations may lead to misunderstandings and it would be advisable to abandon it.

(g) **Theories as to the Causes and Nature of Cancer.** Cancer is a growth phenomenon; to understand the cancerous process completely, a full knowledge of the mechanism, and particularly also of the biochemistry, of normal growth processes would be needed, and moreover, it would be necessary to show wherein cancerous growth differs from normal growth. Our knowledge in these respects is still very fragmentary. However, it can be stated that the cancerous process, like many other vital phenomena, represents a chain phenomenon, in which the first link of the chain is designated as the cause; in many cases, the stimulating factor is considered as the first link and regarded therefore as the cause. But, there is hidden in the cancerous process, another factor, representing the readiness of the tissue substratum to respond with growth processes to stimuli. The degree of responsiveness varies in different cases and also in different types of cells and tissues; primarily, it is determined genetically. In cases in which the state of the tissue substratum is a very important factor in the ultimate cancerous transformation, emphasis has been placed on this condition as the cause of cancer by some investigators. Furthermore, in the course of the cancerous chain process the character of the substratum undergoes certain changes; it becomes sensitized and thus gains in importance at the expense of the significance of the stimulating factors. But the process cancerization is not a simple chain process; it is represented by a very long complex chain in which the stimulating factor continues to act over extended periods of time, either perpetually in small quantities, or intermittently at intervals of different length, and each time it functions it sets into motion a reaction chain. Under normal conditions, life phenomena are cyclic or rhythmic; stimuli cause a change, or a series of changes, which normally end by a return of the system to the original state. But in many cases the end-stage reached in such a cycle is not exactly the same as the state in which the organism was at the beginning of the cycle; the return is not complete, and ultimately this incompleteness leads to certain irreversible changes as those observed in the process of ageing. The chain process leading to the cancerous tissue transformation consists also of a series of cyclic processes, in which in each case the endstage differs from the stage present in the beginning. The substratum is altered continuously, step by step, in a certain direction, until in the end the threshold of cancer is reached, which represents a new and irreversible tissue equilibrium, and, as we have seen, this process may continue in the same direction, even after this point has been attained.

Several phases in this complex chain process are understood, namely, the nature of the initial stimulating factors and, in many cases, also the degree of responsiveness of the tissue substratum; furthermore, the gradual structural and growth changes occurring in the tissues and the process of sensitization are known to some extent, as well as the mode of reaction of cancerous tissues and some of the metabolic accompaniments of the cancerous condition. There are, besides, at least certain indications of the chemical and metabolic changes which are produced by the initial stimulus during the first chain. This, in a general way, is the present status of our knowledge of the cancerous process. If all the elements of this composite chain were known, no theory of cancer, in the sense in which this term has been used in the past and is still used at the present time, would be necessary, the various theories being very incomplete substitutes for a full understanding of the causes and nature of cancer. Especially in the earlier periods, the discussion of theories concerning the causes and nature of cancer played a very prominent role. Yet, on the whole, each one of the older theories merely expressed a single feature more or less characteristic of cancerous

types of growth, at the same time ignoring a number of other equally important, or perhaps even more important, characteristics of this process. Thus, Virchow considered chronic irritation as the cause of cancer; this is designated as the irritation theory of cancer. Cohnheim stressed the importance of abnormal or retarded embryonal development in a certain organ in the origin of cancer, and he thus stated the embryonal theory of cancer. Ribbert compared cancer tissue to regenerating tissue, such as the epidermis during the process of wound healing, but differing from the latter in that the growth-restraining influence of the union of the originally separated tissues, which represents the endstage in the process of healing, is lacking. Cancer would then be tissue which is forced to regenerate indefinitely, and the cancerous process would be a state of regeneration that continues without end. Regeneration of this kind may be induced by chronic inflammatory conditions, or, in other instances, by the separation of embryonal parts during embryonal development. This explanation assumes, then, that cancer cells are essentially normal, regenerating cells, and that they would be able to return to their old normal state if environmental conditions permitted them to do so. However, cancer cells are not normal cells; they behave like cells spurred on to grow indefinitely and to move without rest because of some inner change which they have undergone, or, in some instances, because of the presence within their cells of a virus-like agent.

At the present time, three interpretations of the cancerous process have to be considered. The first theory regards somatic mutation as the essential cause of cancer; the second theory holds viruses to be responsible for cancerous growth. The third theory considers as the principal factor in this process, a series of inner consecutive changes in the cell structure and metabolism, perhaps consisting in an increase or new creation of substances acting as autocatalytic growth stimulators. These changes are connected with and caused by the long-continued growth processes which precede cancer formation, and lead, step by step, to an increased growth momentum and to a sensitization of the tissues, which makes them more and more independent of the specific stimuli in their continuation of these growth processes.

We have discussed already the significance of somatic mutations and of viruses as the possible causes of cancer. The first of these theories subordinates all other causative factors to cell mutations. It is assumed that such mutations occur in the course of the chain events set into motion by the action of stimulating factors. The second theory subordinates all factors concerned with the causation of cancer to the presence and activity of a virus. All other factors are supposed either to activate the viruses, or to prepare the substratum on which the virus acts, in such a way that the virus can fix itself to the cells. While this theory does not state definitely wherein the action of a virus, as for instance, that of the rabbit papilloma, would differ from that of other stimulating factors, such as hormones or carcinogenic hydrocarbons, it seems that in contrast to the latter, which bring about gradual changes in the cells, eventuating in cancer, and which are no longer needed once the cancerous state has been reached, the virus is supposed to be present continuously in the cells and to exert a perpetual growth stimulus on the tissues, which would not need, therefore, to undergo fargoin changes in order to maintain the continuous growth. There is some evidence that the agents of fowl sarcoma may function in this way, but there are, on the other hand, also indications that other viruses may perhaps act as cell stimulators, similar to enzymes and carcinogenic hydrocarbons. The third interpretation was stated in principle by the writer in 1916 and has since then been still further elaborated.

3. *Graded Cell Changes as the Cause of Cancer.* In stating the third theory, we shall recapitulate some of the essential data and conclusions at which we have arrived. This theory considers cancer as the result of step-by-step intensified growth processes, due to the interaction between growth stimuli, graded in strength as well as in time, and a graded responsiveness of tissues and cells which is primarily deter-

mined by hereditary, genetic factors. As a result of this interaction, the threshold of conditions, which makes possible the return of the stimulated tissue to its original equilibrium, is exceeded. In the course of the preparatory growth period, the tissue passes by way of sensitization to precancerous and finally to irreversible cancerous states, of which again there are various degrees of intensity. The ultimate state of the cancerous equilibrium is irreversible. Tentatively, it may be conceived as being due either to the increased, constantly renewed formation of a new autocatalytic growth-promoting substance, not yet present in the tissue in its ordinary equilibrium, or to the intensified production of autocatalytic substances, which are present already in normal cells. While it is not difficult to designate the first two theories which we have discussed by a single term, such as the virus or the somatic mutation theory, because each of these theories considers one single factor as paramount and all other factors as subsidiary, the third theory just mentioned is based on a series of graded cell changes and attempts to combine hitherto, more or less isolated data concerning cancerous growth into one connected system, in which various factors which are considered equally important coöperate. Hereditary, constitutional and stimulating factors, through their interaction, bring about these graded cell changes. However, as stated already, the distinction between these two sets of factors is not absolute, but only one of degree. The stimulating factors produce sensitizations of the tissues, and likewise, hereditary factors may produce in the tissues a primary sensitization to growth stimuli. In regard to the virus-like agent, the so-called milk factor, which coöperates with the stimulating hormones and with the genetic constitution in inducing mammary gland carcinoma in mice, it is not certain to which category it belongs. In general, stimuli of the variable kind, specific and nonspecific, strong and weak, may possess a cancerigenic function. Exogenous viruses like the Shope papilloma virus also seem essentially to exert a stimulating function not unlike that of other cancerigenic agents, such as hormones and the specific carcinogenic hydrocarbons.

The formation of growth substances, which are constantly renewed autocatalytically and which may also stimulate the invasive activity of the cells, might explain the irreversible condition of the cancerous cells, but the gradual increase in this substance, in addition, might be assumed to parallel the gradual increase in growth momentum of the cells during the preparatory growth period under the influence of the stimulating substances. At a certain stage in this process the growth momentum has reached an intensity which makes it possible for the cells to undergo the cancerous changes under the influence of the normal metabolic or mechanical conditions. Moreover, it would have to be assumed that the activity of these self-propagating growth substances would become irreversible as soon as a certain degree of intensity of their action has been reached. This interpretation of the cancerous state which, was suggested by us in 1916 and subsequently, as far as the existence of these autocatalytic growth substances is concerned, is tentative, but the essential underlying principle of the theory, namely, that cancer is the endstage of preparatory growth processes which depend upon the quantitative interaction between stimulating and hereditary factors, and that the hereditary factors determine mainly the intensity of response of certain tissues to stimuli, and furthermore, that this response is a specific characteristic of the various tissues and organs, seems to be in harmony with the essential facts more recently published.

There is then one effect which, as far as we know, all the cancerigenic chemical substances as well as physical agents have in common, namely, that of initiating a preparatory growth period, during which sensitization takes place, and there is only one condition known in which it appears that cancer is initiated without such a preparatory growth period preceding the cancer formation. The agent causing fowl sarcoma seems to represent not a stimulating factor which gradually induces the receptive tissue to undergo step-by-step changes which eventuate in cancer, but in this case the end-factor which directly induces intensified cancerous proliferation, to-

gether with certain metabolic changes characteristic of cancer, is passively transmitted to the cells and begins very soon afterwards to be effective.

In all other instances, as far as is known, the growth processes as such, or processes intimately connected with these growth processes, lead in the course of time to those cell changes which make them the active factors in the development of cancer. That it is the growth processes initiated by the various stimulating agents, or at least phenomena closely associated with these growth processes, which are essential for the production of cancer, is indicated also by the fact that all conditions which accelerate these preparatory growth processes seem, as a rule, to accelerate also the process of cancerization, as shown in the parallelism which exists between the intensity and rapidity of the preparatory growth processes and the readiness with which cancer is initiated, and further, by the fact that hormones which enforce or diminish the normal growth stimulating effects of estrogen, likewise enforce or diminish, respectively, its cancerigenic effects. However, not every growth process causes, as a rule, this transformation; ordinary regenerative changes or certain hormone actions which are quite efficient in producing the formation of new tissue, such as the development of the mammary gland during pregnancy, do not, as a rule, lead to cancer production. The cancerigenic growth processes must be of such a kind that more and more intensified growth reactions take place in the course of time; merely extensive growth which, after a certain period, allows the return of the growing tissue to its original starting point and which represents, therefore, an approximately cyclic process, does not, as far as is known, induce cancer formation. It follows also from these considerations, that in a strict sense there exist no specific cancerigenic substances, but merely growth substances differing in the intensity of their action, and this is true also of the so-called carcinogenic hydrocarbons. The only probable exception to this conclusion known so far are the agents which induce avian sarcoma, and in this case it must be remembered that they affect connective tissue structures, which are, in general, more readily converted into cancer than are epithelial and certain other tissues. However, there still remains the problem as to why different growth-promoting substances differ so greatly in their ability to cause the cancerous transformation of a given tissue. In order to answer this question it would, above all, be necessary to compare the processes taking place during the preparatory growth period initiated by these various compounds.

In general, there is a tendency inherent in tissues and organs of the organism to undergo cyclic changes in response to stimuli; these reactions may consist in functional, metabolic or growth processes. The cyclic nature of these reactions is, however, not perfect, and because of this deficiency the tissues and organs, and the organism as a whole, do not retain their youthful efficient nature, but gradually they approach the conditions characteristic of old age, or, as a result of a similar process, they become cancerous if stimuli which induce marked growth processes interfere with the return of the tissue to the original equilibrium. In certain respects, cancer may then be included among the ageing processes, even in cases in which it develops in young individuals. There is another important point of resemblance between cancer and the ageing of the organism as a whole. One of the characteristic features of old age is the partial dissociation which occurs in this condition in the harmony of the well organized functional and, in particular, metabolic interactions between the various constituents of the normal body in its youthful state. In the course of life, injuries and deficiencies develop in various organs and tissues, which proceed with unequal rapidity among these different components. These disturb the normal interaction and the harmony between adjacent tissues, as well as the interactions between distant organs, and as one of the results of this disturbance, cancer may develop. The cancerous condition quite commonly is designated as one of autonomy of a component part of the body, which was formerly dependent on regulations emanating from tissues directly surrounding it and also controlled by regulations

originating in distant places. However, in reality cancer does not represent a cell community that is autonomous in the strict sense. There is a diminished cohesion, or even a lack of it, between the units composing the cancerous tissue to which a state of autonomy has been attributed, and there is no general or local control over the individual cancer cells within the cancerous formation. The actual condition is, rather, one of more or less advanced dissociation between the constituents of the cancer tissue. The fact that in cancerous growth a certain part of a tissue becomes independent of the central organizing factors in the organism and independent also of the restricting effects of contact with neighboring tissues, is primarily the result of the predominance of the stimulating over the restricting factors in the life of the affected cells and tissue. Even long-continued, rhythmic stimulations may accomplish this effect, if there is a strong reactivity of the tissues to these stimuli, or if there is a summation of slight deviations from the complete return to the resting state of the tissues.

These conditions obtain notwithstanding the fact that cancer may appear in some instances in young individuals. This occurs if the dissociative processes set in in early life, under conditions in which the stimulating factors are very active and if, in addition, the genetic constitution of the individual is favorable to the dissociative effects of the stimulating processes. In certain cases, the dissociative processes affect embryonal cells, or even germ cells, and here likewise the cancerous state may be reached in a young organism.

While sensitization of tissues during the preparatory growth period is an indication of the continuously increasing effectiveness of the tissue stimulation, on the other hand, immunity, developing either in the tissues themselves or in distant organs, specifically endowed with the ability to produce immune substances of various kinds, tends to cause the return of the reactions to their starting point and to render them approximately cyclic. These immune processes must therefore be overcome if cancer is to develop as a result of the long-continued growth reaction. The ability of the stimuli to induce non-cyclic processes, at last leading to irreversible cancerization, depends upon three conditions: (1) the nature and intensity of the stimulations, (2) the kind of substratum on which they act, and (3) the character of the stimulus-reaction circuit. We have already discussed the various types of stimuli which may be cancerigenic. But we shall here once more state the differences between hormones and carcinogenic hydrocarbons in their function as cancerigenic stimuli. Hormones may initiate cancer by exerting their normal growth-stimulating functions on organs to which they are specifically adapted; secondarily, and much less effectively, they may in some instances exert a cancerigenic action on connective tissue or leucocytes; this effect is perhaps due to a chemical relationship of these hormones to carcinogenic hydrocarbons, and it is different from their primary cancerigenic action, which is based on their physiologic function. Carcinogenic hydrocarbons act on tissues with which they come into contact rather indiscriminately; they lack to a very large degree the tissue or organ specificity and they do not normally exert physiological functions as growth stimulators; but some of them possess what might be designated as an intensity specificity, acting on the tissues with which they are in contact with great intensity. There is therefore no reason to assume that a hidden carcinogenic hydrocarbon is the cause of all types of spontaneous cancer; in fact, the only spontaneous cancer in which an endogenous chemical factor is known as the cause is the hormone cancer; it is due to substances which occur normally in the healthy organism, and the discovery of hormones as cancerigenic agents and of their mode of action preceded that of the carcinogenic hydrocarbons, which differ in their cancerigenic action in some important respects from the hormones. The search for carcinogenic hydrocarbons as the cause of spontaneous cancers is based on the supposition that they are the only potent cancerigenic factors. However, as stated, these compounds are not in the strict sense carcinogenic substances; like all other

cancer-producing agents, they are in all probability primarily growth substances. Many stimuli may initiate growth processes and thereby cause the production of cancer. The more specific factor in this process is evidently not the nature of the stimulating factor and its mode of action in calling forth growth processes; the most specific factors are those which are common to all cancers, and the essential problem concerns the question as to how and under what conditions the transition from the preparatory growth processes to cancer takes place and whether there are processes associated with these growth phenomena which are required for this transition. The mechanism through which these stimuli set into motion the preparatory growth processes may vary according to the kind of stimulus which is applied, and it is presumably of secondary significance as far as the production of cancer is concerned. Conditions are different in this respect, if we consider the mode of action of infectious diseases; in these, the initiating factor, the microorganism, is of primary importance; it is the most specific factor and largely determines the nature of the disease which follows its entrance into a host, in contrast to cancer where the various types of stimuli all lead to the same kind of pathological change, in which the symptoms and the outcome are the same, irrespective of the factor which set this sequence of events into motion.

As to the inherited individual, strain and species differences in the substratum, these are very potent in modifying the results of stimuli. Thus, in the mouse and guinea pig the effects of estrogen on the mammary gland differ greatly. In the former, long-continued application of estrogen initiates the active growth processes only very slowly, and then, step by step, these reactions are intensified, until in the end cancer is produced. But even in the mouse the effectiveness of these stimuli differs greatly in different strains. On the other hand, in the guinea pig the early results of the stimulation of the mammary gland by estrogen are relatively much more marked than in the mouse, but after some time these growth effects come to a standstill and no further proliferation takes place; the tendency to the formation of mammary gland carcinoma under the influence of estrogen is lacking, or at least is very weak in this animal. The growth curves of the mammary gland caused by ovarian hormones differ in these two species, and, correspondingly, the readiness with which carcinoma develops also differs. Moreover, the differences in the physiology of various tissues are important factors in determining the readiness of these tissues to become cancerous. Thus connective tissue cells seem to respond as a general rule, more readily to stimuli of different kinds with cancer formation than do epithelial structures. Stimuli of a nonspecific nature may be effective in the former to a much greater extent than in the latter. It will therefore be necessary to know fully the physiology of various tissues in order to understand the difference in the readiness with which they may become cancerous. In regard to the third point, the reaction curves are different in different growth processes, as for instance, in the regenerative growth process and in embryonal development. In some instances the initial element in two growth chains may differ greatly, while the end-results may be the same. Thus injuries, leading to defects in the tissue, may initiate growth processes, and, likewise, hormones may be able to do so, but without depending upon primary injurious conditions for their effects. These differences in the character of the stimulus-reaction circuits in different types of growth processes, affect as well the manner in which the various types of growth finally change into cancerous growth.

This interpretation of the cancerous process has to meet one difficulty. According to all the data known at present, it is characteristic of cancerous cells that they retain their specific reaction modes and transmit them perpetually to the following cell generations. Thus, cancerous cells may die but they do not seem to revert to the state of normal cells. This point has been proven especially by means of the continuous serial transplantation of tumors; but it agrees also with the observation and experimental study of individual tumors. It is furthermore certain that the cancer

cells develop from normal cells, which thus transmit their newly acquired characteristics to their descendants from generation to generation. This seems to contradict the findings in unicellular organisms where acquired characteristics survive, at best, for a considerable number of generations but ultimately lose again these acquired properties ("Dauermodifikationen" of Jollos). In protozoa, according to the interpretation of Jennings, the return in these cases to the original condition of the cells is presumably due to the controlling effect of the nucleus over the cytoplasm. It should then be possible to perpetuate a newly acquired characteristic of a whole cell or of the cytoplasm, provided the constitution of the nucleus is not opposed to this alteration. Such a condition is realized during embryonic development, when changes take place in cells which are irreversible and the endstage of which may be transmitted from generation to generation. The egg ultimately becomes converted into various types of cells, such as those of thyroid or epidermis, and there is every indication that this change—an acquired condition—can be transmitted indefinitely to successive generations of cells. Even intermediate developmental stages, as for instance, the characteristics of an embryonal tissue cell, which is also derived from mother cells possessing entirely different characteristics, can be propagated endlessly in tissue culture. In all these instances it seems that the nucleus and the rest of the cell cooperate. However, it must be noted that these changes take place only when they are in accordance with the genetic constitution of the organism of which the cells involved form a part. Correspondingly, we would have to assume that in order to be permanent, also the transition from the state of a normal cell to that of a cancerous cell would have to be in accordance with the genetic constitution of the individual to which it belongs; and that not only ageing in general, but likewise the cancerous growth would represent a continuation of embryonal development in the same sense as other ageing processes. The formation of cancer may therefore be considered as an endstage in the ontogenetic evolution of cells or tissues which occurs under certain conditions.

As stated previously, it would then be necessary to assume as preformed in the genetic constitution of the organism, the existence of two principal cell equilibria: (1) the equilibrium of the adult, normally functioning cell, and (2) the cancerous equilibrium. These two equilibria are joined to each other by intermediate stages, represented by growth processes of varying intensity and by processes of sensitization. The beginning stage, the various intermediate stages, and the endstage may be considered as a connected series comparable to the stages leading from young adult tissues to those of the senescent organism; these again are joined together by intermediate stages and they all are potentially determined by the structure of the fertilized germ cells. Furthermore, in accordance with our earlier interpretations of the cancerous process, it would be possible to conceive of the cancerous equilibrium as being due to the increase in, or to the new creation of, autocatalyzers capable of intensifying cell growth. Associated with the stimulation of growth processes there may take place also a stimulation of ameboid movement, which may help in the transfer of the cancerous tissues to various parts of the body, and which at the same time may intensify the disorganization of these tissues.

The interpretation of the phenomena of cancerigenesis has, then, narrowed down to the consideration of the virus theory of cancer and of the theory of cancer as representing the endstage of a series of graded cell changes, due to stimuli exceeding the threshold permitting normal growth and acting on a tissue substratum endowed with the potentiality to sensitization, which varies in degree in different individuals in accordance with the genetic constitution. Such stimuli may be supplied, also, by certain viruses. There are in addition the agents of fowl sarcoma, which seem to induce the cancerous transformation directly. It is possible that these viruses instead of being living microorganisms, represent very complex macromolecular proteins associated with other groups, such as nucleins. The possibility exists,

furthermore, that they originate in the higher organisms, in which they act and function here directly as cancerigenic growth stimulators; but in contrast to other growth substances which originate and multiply within the cells, they can be transferred to other individuals of the same, or nearly related species, whose tissues they are able to invade. These viruses would thus act in a similar manner to the autocatalytic growth substances, which ultimately also would transform a normal into a cancerous cell. If finally it could be shown that the agents of fowl sarcoma and the autocatalytic growth substances act in a comparable manner, the difference between these two theories would be greatly diminished. On the other hand, the ability of viruses to undergo adaptive changes after transfer to different types of hosts, in accordance with the observation of Duran-Reynals, seems to be more compatible with the concept that viruses are real organisms, able to pass through ultra-filters, than that they are protein substances. However, the experiments of Pauling and his associates, which indicate that serum globulins, through contact with various cell constituents, can be changed into immune substances which act specifically on the constituents with which they have been in contact, suggest that also complex protein molecules may be self-propagating and readily undergo changes of an adaptive character. However, these considerations are at present of a purely hypothetical nature. Future investigations must determine whether all or the large majority of tissues represent symbionts between cells and viruses, or whether various types of cell equilibria exist, of which the cancerous equilibrium represents a possible endstage potentially present in all tissues endowed with the ability to proliferate, an endstage which is activated by stimuli exceeding certain thresholds which lead to the perpetual acceleration and intensification of the processes underlying cell multiplication and ameboid movement. The nature of this threshold and the mode of reaction of the various tissues to such stimuli are essentially determined by genetic factors.

Gerontology: The How and Why of Ageing *

A. J. CARLSON †

Department of Physiology, University of Chicago

The science of biology and medicine has not yet reached the stage when a factual chapter on the physiology of ageing can be written. At the end of an excellent fifty page review of the chemical aspects of ageing, McCay concluded (1939) that "almost nothing is known of the biochemistry of ageing." The physiologist need not be quite so pessimistic, but instead of writing on what we do not know, biochemists and physiologists might be better employed in research on these important unknowns.‡ Many age changes in the animal body have been clearly established. The cause or causes of these age changes in structure and function are still obscure. We are not in a position to determine to what degree the changes in the machinery of the body, which parallel advancing age, are due to the genetic constitution of the individual and the species; that is, to the ageing process *per se*, and how much are due to the accidents of living, such as faulty diets, infections, overwork, laziness, gluttony, and what have you. As regards the life span of the species, plant or animal, undoubtedly the genetic constitution plays the primary role, for on no other basis can we account for some species of plants living only one year or less and other species living several thousand years. Disease and other accidents of living cannot account for such great differences in life span in plants, nor can it account in my judgment, for similar differences in the life span in different species of animals.

There is growing evidence that the hereditary constitution is also a factor in the life span of individuals within the species, irrespective of ignorance, faulty diets, infections, and other accidents in the life of the individual. This appears also to be true for the life span of individual organs in the individual. For while it is true that faulty diets, infections, etc., may hasten the atrophy of the ovaries in primates and thus bring on a premature menopause, that similar accidents and disease may hasten the loss of elasticity of the lens of the eye, it is nevertheless true that the life span of these two organs, the primate ovaries and the lens of the eye, run on the whole such a fairly regular course in the individuals of the species that the early atrophy of the ovaries in the female and the relatively early decrease in and loss of elasticity of the lens can hardly be accounted for by the accidents and stresses in

* As this Chapter is written primarily for Physicians, familiarity with the normal physiology of the human adult is assumed, or can be renewed by the aid of any up-to-date medical textbook of physiology, biochemistry, and physiologic pathology. The lay reader may find this volume a useful aid: *The Machinery of the Body*, by A. J. Carlson and V. Johnson, University of Chicago Press, revised edition, 1941.

† Parts of this essay will appear in a volume on geriatric medicine, Dr. E. J. Stieglitz, Editor, Saunders Co., 1943.

‡ Some colloid chemical aspects of ageing are referred to by H. Schade and by A. Lumiere in Vol. II of this series. Dr. Carlson's authoritative summation of the clinical aspects and their interrelations poses many problems which must be considered in the light of a number of the theoretical and biological papers in this series. The statue by Gian Bernini (Borghese Gallery, Rome), representing the stalwart Aeneas carrying the shrunken form of his aged father Anchises and leading his chubby son Ascanius, beautifully illustrates the results of the complicated colloid chemical changes involved in ageing. J.A.

the life of the individual. The life span of these two organ systems must be primarily determined by the physiological time clock, perhaps particular genes of the hereditary constitution. But when we consider the other organ systems of the body, the slowing up of function, or the impairment of function is on the whole so gradual (at least in all cases where the life of the individual is not specifically terminated by *overwhelming* accidents in individual organs such as malignant growths, gastric ulcer, pneumonia, tuberculosis, nephritis, or arteriosclerosis) that it becomes practically impossible to separate the factors of ageing from the factors of impairment due to the accidents of disease. Of course, the germ cells themselves may be acted on unfavorably by the accidents and strains of living, and the poisons of metabolism, even though the germ cells are not the link in the life chain of the individual; at least this may be so in the case of the species. If this were true in the case of the species, we would have degeneration of species and shortening of the life span of the species and this would be a rule instead of the exception. The relative importance in the life span and in the process of senescence of the genetic constitution as opposed to the environment is illustrated by the fruit fly, where, with the identical environment but with experimentally modified genetic constitution, the life span may vary as much as 400 per cent, the most extensively modified genetic constitution leading to the earliest senescence. To be sure, it is a long distance from the fruit fly to man, and by and large, science has yet been able only to degrade rather than to strengthen the genetic constitution by experimental means. Nevertheless, similar factors probably play a role in the phenomena dimly foreshadowed in the life of man, that is, in the relatively long lived and relatively short lived human families.

If further justification of our primary thesis, namely, the practical impossibility of separating the factors of ageing *per se* from the effects of the accidents of living is needed, we might cite the case of many plants in which the tissue degenerations once thought to be due to ageing (that is, to the genetic constitutions) seem now to be due to virus disease, an injurious factor in living, of which we have at present only the scantiest of information. And in plant seeds, age degeneration seems to be due to progressive chemical changes in the cell nuclei, changes which in turn interfere with cell division and growth.

Unicellular animals are commonly said to be immortal. Nevertheless, these lowly cousins do seem to degenerate with age. Again, this degeneration appears to be in the physiologically active nucleus, and unless this aged nuclear material is replaced by the reserve micronucleus, as occurs in conjugation and endomyxis, decline and death of these unicellular organisms seem inevitable.* This is, in principle, not so different from sexual reproduction and death of the soma or body in the higher plants and animals.

Despite this discursive and disappointing introduction, the following principal age changes in the physiology of man and other animals can be listed, appearing at different age levels in the individual and at different age levels in the organ systems of the individual. The universality of these age changes, even in individual persons whose hereditary constitutions have been able to meet the accidents of living for 100 or more years, renders it highly probable that we are here dealing with age changes primarily inherent in the constitution of living matter, no matter how greatly they may be speeded up by the accidents of living.

Progressive age changes, not as yet shown to be due to specific diseases:

1. Gradual tissue dessication.
2. Gradual retardation of cell division, capacity of cell growth and tissue repair.
3. Gradual retardation in the rate of tissue oxidation (lowering of the B. M. R.).†

* See paper by H. S. Jennings in this volume. J. A.

† B. M. R. is basal metabolic rate, that is the rate of oxidation when the body is at rest and the individual has rested reclining at least 30 minutes prior to test. No food should be taken over the preceding 12 hours.

4. Cellular atrophy, degeneration, increased cell pigmentation, and fatty infiltration.
5. Gradual decrease in tissue elasticity, and degenerative changes in the elastic connective tissue.
6. Decreased speed, strength, and endurance of skeletal neuromuscular reactions.
7. Decreased strength of skeletal muscle.
8. Progressive degeneration and atrophy of the nervous system, impaired vision, hearing, attention, memory, and mental endurance.*

This picture of ageing is, in fact, not as dark and depressing as it seems, for the following reasons: (1) An efficient mental life is possible, even with reduced factors of safety. (2) Moderation in all things, plus competent medical guidance in regard to the accidents of disease will tend to prevent undue corrosion of specific life links, so that all of them pass down the hill gradually and in step. (3) The man or woman who has passed the first 60 or 70 years in honest toil and persistent efforts at understanding has accumulated a *great reserve of wisdom*, now at the disposal of the younger generation; a reserve of wisdom which antidotes the stresses and strains induced by the fears, the vanities, the greeds, and the ignorance of the earlier years. This is true at least up to the point where the impairment of cerebral function leads to the so-called "second childhood." Intensive research on the many unknowns in the ageing processes will some day enable the science of medicine to delay greatly this involution. This is not "rejuvenation" either in the popular or in the medical quack sense. *It is merely better care and better driving of the living machine, provided by our growing understanding. This is the goal of geriatric medicine.*

The Digestive System

The salivary glands usually show some evidence of atrophy with advancing years, and competent investigators have reported definite decrease in salivary volume and in percentage of ptyalin with advance in age. This is not a vital link in the life span since most animals have no ptyalin and we can adequately digest all our food without the aid of ptyalin, the most important constituent of saliva being the water and mucin. To what extent the decrease in saliva or the age changes in the composition of the saliva permit or favor growth of the aciduric flora of the mouth, which in turn predispose to caries and enhance degenerations in teeth and of gums, is still an open question.

The work of Blumfield and Poland indicates that from the age of 20 years on, the volume and the acidity of human gastric juice decreases definitely but gradually, and it is well established that the incidence of achlorhydria increases with age. Thus achlorhydria appears in only about 5 per cent of people under the age of 20 years, while it appears in 35 per cent in population above the age of 60. Again, we must note that the higher incidence of achlorhydria with age may be due to the accidents of living rather than to the process of ageing. Nevertheless, the existence of achlorhydria in a child of 5 and the presence of hydrochloric acid normally in gastric juice of a person at the age of 100, points to an hereditary time clock in this function of the gastric mucosa, as the primary factor, no matter how greatly this time clock may be accelerated by the accidents, the ignorance, and the follies of living.

It is also well established that the incidence of pernicious anemia increases with age, indicating in all probability an ageing factor in the gastric component or intrinsic factor of red cell formation. The gastric pepsin factor seems less subject to ageing and to the accidents of living than does the hydrochloric acid factor.

* These changes are not listed in the order of their primary significance, for this is not yet known. Nor does the list imply that these are all the changes of senescence. It is already evident that ageing is a continuous and complex process, some changes starting early, others later in the life of the individual.

On the motor side of the stomach, in the absence of such diseases as cancer or ulcers, there is little clear evidence except that dealing with the strength and rate of the contractions of the empty stomach, that is, the so-called hunger contractions. These do definitely decrease with age, as shown particularly in man and dog. The periods of relative motor quiescence of the empty stomach are shorter in the young, become much longer in advancing years, and the periods of active contractions shorten, and the contractions themselves become feebler with advancing years. But this evidence of impairment of gastric motor activity with ageing appears to be sufficient to cause significant delay of the emptying time of the stomach, but not significant enough to produce impairment of digestion.

Atrophic gastritis might readily be a chronic effect of dietary indiscretions if not of chronic infections, such processes wearing out, as it were, the regenerative or recuperative capacities of the gastrointestinal mucosa. However, there is no good evidence of any gradual increase of atrophic gastritis with age.

In the case of the pancreas, the incidence of diabetes increases with advancing years, at least up to 50 or 60. The pancreas shows many scars from accidents and injury of living. Goodpasture has described degenerative changes in the pancreas of old dogs and similar changes have been noted by Allen and others in post mortem examinations of elderly people dying from a variety of causes. But we have no reliable data on deficiency of pancreatic juice or pancreatic juice enzymes with advancing age uncomplicated by pancreatitis, liver, or biliary tract disease. The fact that in some individuals, diabetes may develop in early childhood, while in other individuals the hormone mechanism of the pancreas is able to meet the metabolic need of an individual 100 years old, might induce one to conceive that the failure of this phase of pancreas function with increasing age, is due to hereditary weakness rather than to the accidents of living or duration of life.

While the gross weight of the liver decreases with age, at least from the fourth to the seventh decade, the present available liver function tests do not reveal any liver impairment with ageing in the absence of specific liver disease. In fact, the liver of an old dog appears to be more resistant to the injurious effects of chloroform than is the liver of a pup, as is also clearly the case in the human species. But it is well known that the incidence of liver pathology increases with age and there appears to be some decrease in concentration of vitamin C in the liver with the advancing years. Whether or not this is secondary to decreased absorption of this vitamin from the intestine is not known. The incidence of gall stones increases with age, but the gall bladder, free from disease, apparently empties normally even in very old people and very old animals.

There appear to be no reliable data on atrophic changes in the mucosa and in the musculature of the small intestine with advancing age. To be sure death from intestinal obstruction increases with advanced age, but this may be due to adhesions rather than to weakness in the intestinal musculature. Atrophy of the colon musculature with advanced age is uncertain. The motility and absorption in the colon appears normal in the aged in the absence of definite colon disease, but diverticulosis of the colon seems definitely to increase with age from the fourth decade on. This may indicate atrophy or decreased tone of the colon musculature or decrease in the elasticity of the connective tissue layers of the colon. According to Dr. Ivy, "Death in the aged is apparently only rarely due to the wearing out of the organs of the digestive system. In the absence of gastro-intestinal cancer or local toxic or infectious processes, the digestive system seems capable of functioning beyond the ordinary life span."

The Cardio-Vascular System

Failure of health to the point of death, primarily due to failure of the cardiovascular system, is known to increase with age, at least beyond the fourth or fifth

decade of life. At the same time both cardiac and blood-vascular efficiency may persist in man to a degree rendering life possible, if not efficient, at the age of 100 years. But in the way of comparison, either the hereditary time clock is shorter or the accidents of living are more serious in the case of the cardio-vascular system than in the case of the digestive system. Also, at present, it is somewhat more difficult to separate purely age factors from accidental disease in the cardio-vascular system.

Instead of atrophy with age, there is, with advancing years, an actual increase both in size and weight of the heart—due in part perhaps to cardiac incompetency, even when the increased fat in the heart of old people is deducted, but this does not mean increased efficiency; in fact, it may be secondary to cardiac incompetency. There is decrease in the elasticity of the heart valves, and increased calcium or cholesterol deposits in the valves. There is increased thickness of the endocardium, there is an increase in brown pigment in the muscle cells, and a diminution of the cross striation of the muscle cells, especially close to the nuclei.

On the functional sides, cardiac irregularities such as premature contractions and auricular fibrillations show a tendency to increase with advancing years. Cardiac irregularities from hyperthyroidism are more frequent after the age of 45, and, while this may be an indication of decreased cardiac reserve, it may also mean an increased incidence of hyperthyroidism beyond that age. There is a decrease in oxygen consumption in the heart with advancing years, the heart in this respect showing a parallel with the gradual lowering of the general basal metabolic rate of the body as a whole. The electrocardiogram shows lessened voltage and some slowing of conduction in old people. This probably indicates some impairment of the conduction system. On the other hand, there appears to be an increased sensitivity of the carotid sinus and depressor cardio-inhibitory reflex with the advancing years.

Where spasm or atheromatosis of the coronary arteries intervene, we obviously have the same impairment of the heart as occurs in all other tissues where the efficiency of the circulation is impaired, by chronic functional spasms of the blood vessels, or by mechanical narrowing of the lumen and by decreased elasticity and calcification of the blood vessel walls.

The old saying that a person is as old as his arteries is still partly true. There is decreased elasticity of the aorta, decreased elasticity and increased calcification in all arteries in all people with advancing years. But these ageing degenerations or disease factors do not appear to the same degree in all arteries at the same age in the same individual, or to the same degree at the same age in different individuals. So here again we are faced with the problem, how much are these arterial impairments due to ageing *per se*, and how much to the accidents of living. If it should turn out, as the work of L. R. Dragstedt indicates, that one main factor in the genesis of arterial sclerosis is faulty fat metabolism induced by the deficiency in a hormone or hormones necessary for normal fat metabolism, we are well on the road to a partial understanding and possibly prevention of this well nigh universal corrosion of a vital link in the life chain of the individual. Snapper suggests that the practical absence of meats and milk in dietary of the people in North China may be a factor in the low incidence of arterial sclerosis in that population. In view of the work of Dragstedt, the overall low caloric diet in that part of China may be a more significant element.

Owing to the gradually decreasing arterial elasticity with increasing age, there is a gradual increase in the speed of propagation of the arterial pulse rate from an average of little over 6 meters per second at the age of 20, to around 8 meters per second at the age of 60. Parallel with these changes in the structure and function of the blood vessels, there is, at least beyond the age of 40, a gradual increase in the systolic blood pressure even in the absence of so-called essential hypertension and in the absence of an excess rate of the heart beat. Some investigators have estimated

this rise in systolic blood pressure beyond 40 as around 1 mm of mercury per year. This is, of course, subject to a great deal of individual variations and to many exceptions, since the systolic blood pressure depends not solely on the condition of the arteries, but also on the efficiency of the heart and on the cardio-regulatory reflexes. Judging from the appearance of the capillaries in the human skin, there appears to be decreased cellular tone leading to capillary dilatation with advancing age. In the kidneys, actual atrophy of the capillary tufts of the glomeruli with advancing age has been described.

The Kidneys

The kidneys, like the digestive system and the cardio-vascular system, serve the entire physiological economy of the individual, hence serious age impairment of either necessarily impairs the function of all. The kidneys show progressive reduction in weight after the fourth decade. The rat's kidneys show progressive involution of the glomeruli after the fourth month of life. In some fish the glomeruli disappear entirely in later life, and the renal organ becomes an aglomerular kidney. The one year old rat exhibits about 50 per cent reduction in hypertrophy of the remaining kidney after extirpation of the other kidney, as compared to the renal hypertrophy of the remaining kidney following this operation in rats only 30 days old. McNider has shown that the kidneys of old animals display increased susceptibility to injury by poisons (ether, chloroform, uranium), and decreased power of regeneration after such injuries. But whether this impairment of growth and repair is primarily a matter of the hereditary renal time clock or aggravated by the accidents of living is an open question.

In the ageing individual, renal involution or atrophy (tubular and glomerular) appear to be secondary to impairment of renal blood flow due to structural involution of the renal blood vessels. But despite such renal histo-pathology of the ageing man, the kidney usually has sufficient reserve, in the absence of specific renal disease, to meet the requirements of the individual at the age of 100 years and beyond. It is now well established by Goldblatt and others that decreased renal blood flow initiates functional hypertension of renal origin. Is this renal anemia (ischemia) initiated or merely aggravated by the accidents of living, that is, is it an unavoidable turn of the renal time clock of the individual? The fact that some individuals can reach the age of 90 to 100 years without sufficient renal ischemia to induce hypertension would seem to indicate that the accidents of living are by themselves not a sufficient cause for this type of renal failure. But it is clear that the serious affliction of the renal life link, by inducing chronic hypertension and further impairment of the circulation, will seriously accelerate the depletion of reserves in all other organs and not only shorten the life span but seriously weaken the life of the aged, years before the death of the individual.

The Neuro-Skeletal System

The gradual slowing and weakening of reflexes and general body activity in the ageing mammal is so obvious as to be well known both to physicians and laymen. Decreased functional capacity both in the nervous tissues and in the skeletal muscular tissue seems to be at the base of this gradual decline. Actual atrophy of the Purkinje cells of the cerebellum has been described in the aged and, since this part of the nervous system is seriously concerned with skeletal muscle tone and coördination of skeletal muscle contractions, it may be a factor in the growing muscular weakness of old people irrespective of the cause or causes of this atrophy in the cerebellum.

As regards the cerebrum of aged people, general atrophy has been described especially in the frontal and occipital lobes, and actual disappearance of cells in

some of the layers of the cerebral cortex, as well as pigmentation and fat infiltration of the nerve cells and actual hyperplasia of the neuroglia cells. Similar degenerative changes with age occur in the spinal cord, that is, atrophic pigmentation, actual loss of cells, and degeneration of the axones of many ventral horn cells. In the case of the brain, thickening of the meninges occurs with advancing age, but it is difficult to see how this in any way should interfere with nervous action or nervous function.

Recent investigations appear to demonstrate a very gradual but significant decrease in the myelinated fibers of the dorsal nerve roots with advancing age. This must be secondary to an atrophy and death of spinal ganglion cells and is probably the basis of the reduction in cutaneous and protopathic sensibility of aged people. The sense of pain seems to be the least affected by ageing. In view of such evidence of atrophic and degenerative changes in the central and peripheral nervous system, irrespective of the primary cause or causes of these changes, it is not surprising that neuromuscular weakness, slowing of the reaction time, decreased capacity to learn, etc., etc. is part and parcel of the physiology of ageing. The speed of learning seems indeed to decrease gradually in man from the fourth decade on. But this handicap of the aged is on the whole more than made up for in some individuals in their greater speed of correlation and evaluation of the new experience.

There is very little evidence of ageing changes in smooth muscle. Smooth muscle seems on the whole to retain its normal histologic character into advanced old age. The diminished tone in smooth muscle, as may be seen in the blood vessels in the gut, and in the smooth muscles of the skin and other structures in old people, may be secondary to the impairment in the nervous system, indicated above. But not all the impairment of body motility with age can be ascribed to the degenerate changes in the nervous system itself because the striated skeletal muscle system shows fatty infiltration and brown atrophy with advancing age. The strength of the biceps at the sixth decade of life is only about 50 per cent of that at the age of 25 to 30. The trunk muscles decline in power somewhat slower. However, the recent investigation by Kubo (1938) reports little evidence in decrease in muscle strength and endurance in people that would ordinarily be called old, that is, people 70 to 90 years of age. There is some increase in connective tissue and elastic fibers in the skeletal muscle of old people and there is clear evidence of dessication, that is, decrease in intracellular fluid. But in this respect, the skeletal muscle of the aged falls in line with all the other tissues of the body.

Vision and Hearing

Because of the accessibility of the organs themselves and the availability of quantitative tests of functions, we have more accurate information regarding the ageing changes in the physiology of the eye and the physiology of the ear than is the case with most of the other systems in the human body.

(a) Vision: In the case of vision, there is a gradual decrease in visual acuity (central vision), and a gradual narrowing of the visual field, as well as a slowing of the dark adaptation (peripheral vision), and a gradually higher threshold for light stimulation for man past the fourth decade. The narrowing of the visual field is probably due to the actual degeneration of the nerve cells (cones), starting in the periphery of the retina. We are not yet in a position to say whether these visual impairments occur independent of, or are secondary to, impaired retinal circulation.

It is equally well known that the incidence of cataract increases with age irrespective of whether or not the tendency to cataract formation is hereditary. Arterial sclerosis would undoubtedly accelerate any such hereditary weakness, and so would certain faulty diets and certain endocrine and other metabolic disorders.

The gradual decrease of the elasticity of the lens is another well known and

accurately measured phenomena of ageing man, with this exception that diminution in lens elasticity actually starts in childhood and practically all lens elasticity is lost before 60 years of age. The lens continues to grow at the periphery (vertex), and thus approaches closer and closer to the cornea with advancing years. At the same time the material at the center of the lens becomes more dense. Both of these factors, and the lens swelling from increased water content, are responsible for the well known phenomena of so-called "second sight" of people 60 years of age and beyond. This lens change tends to counteract the presbyopia, or impairment of accommodation, due to the loss of lens elasticity.

Other age changes that may contribute to the gradual impairment of vision with age are diminished translucency of the cornea and of the vitreous humor. It need not be pointed out that the retina, being actually a lobe of the brain, is necessarily as seriously impaired by local vascular pathology as is any other part of the brain. However, because of the accessibility of the retinal vessels to direct inspection, we have probably earlier factual information regarding such pathology in the retina than we have in most of the other deep organs of the body.

(b) Hearing: From the age of about 20 on, there is a gradual loss of acuity to all tones, but the loss of sensitivity is greater to the high tones. This deterioration of hearing is somewhat greater in the male, but the degree of retrogression is not predictable in chronological age, as some people at 80 have no greater auditory impairment than other normal people at 50. This impairment of auditory acuity is present even when tested by bone conduction. The cause for this decline in auditory acuity appears to be a gradual but distinct atrophy of the nerve cells in the basal coil of the cochlea. But anemia, due to incipient arterial sclerosis, may also be a factor, since in experimental anoxia, the perception of the high tones goes out first.

We have at present no information regarding impairment of vestibular reflexes with advancing years. One would expect such impairment on the basis of the evidence of age atrophy in the central nervous system.

The Endocrine System

The Gonads: Owing to the relative ease of observation as well as experimentation and measurements of such phenomena as menstruation, size and function of secondary sex characters, libido, sex behavior, etc., we have the clearest information, at least regarding the factor of ageing, in the case of the ovaries and the testes. In the case of the gonads, we have the additional special phenomena, that, irrespective of their probable role as hormone producers during intrauterine life and the preadolescent years, they are organs that attain their special function rather late and lose their function rather early in the life of the individual. It is now certain that the gonads are not a link in the life chain of the individual, their absence does not shorten the life span. Prolongation of youth, or of life itself, by gonad hormone therapy is a mirage, a product of wishful thinking.

The rate of decline of the human ovaries at the normal menopause may be as speedy as a few months or may be as prolonged as a few years, this varying with the individual woman. When ovarian atrophy appears much earlier than the 35th to 45th year, one can usually find specific disease contributing to such decline, although we cannot with certainty eliminate specific hereditary weakness in the constitution of the individual, except where destructive tumors or serious impairment of thyroid or pituitary function are clearly involved. The life span of the testes is longer and the decline is more gradual. The hormone production mechanism in the testes, the factor involved in libido and copulation, appears to fail earlier than the spermatogonia and the sperm producing factors. At least in individual instances in the human male, sperm production (not necessarily normal sperm) has been described up to, if not beyond, the ninth decade of life. In the ageing human testes, the basement membrane of the tubules is reported to grow thicker, and the

spermatogonia change or retrogress into the small round cells seen in the immature testes.

In the case of the interstitial cells, increased pigmentation has been described in the old testes. But there is at present no evidence of decrease in the number of interstitial cells. It is difficult to interpret the usual decrease in libido and sexual potency in the aged human male as related to the gradual atrophy of the testes, in view of the fact that in some males between 20 and 35, libido and sexual potency appear to persist to some degree even after total castration. In other words, the mental and vasomotor conditioning associated with the above physiological processes apparently can persist in the total absence of the primary conditioning factor, the male hormone.

Increased pigmentation and gradual atrophy of the acini of the prostate gland have been described in old people and old males of other species, but there appears to be no decrease in gross size of the prostate, despite the fact that castration in the young male leads to atrophy of the prostate and its adnexa. We are here facing the well known dilemma in this physiological system, namely, the dependence of the prostate on the male hormone during adult sexual years, the independence of the prostate of the male hormone during the later decades of life, and the frequent appearance of actual prostate hypertrophy parallel with the decline of the testicular function in old men.

Thyroid. As regards this endocrine gland, we have evidence indicating some shrinkage in size and some evidence of cellular atrophy in the thyroid in old people and old animals. Some people have inferred that this is a factor in the decreased oxidation of tissues with advancing years, but since the thyroid of youth and adult life have such large factors of safety or reserves, we must have more direct evidence than this for such a far reaching conclusion. So far as we know, the thyroid gland even of very old people is capable of meeting the hormone needs of the body, in the absence of specific thyroid disease or iodine deficiency in the diet.

Pancreas. In the case of the pancreas and insulin, the evidence of increased histopathology in the pancreas with advancing years, the fact of increased incidence of actual diabetes, at least up to the age of 50 or 60, as well as the gradual decrease in sugar tolerance with advancing age, as evidenced by the glucose tolerance tests, all these facts point to some ageing in the insulin producing mechanism parallel with the advancing years. The perennial puzzle in this field is the evidence in such animals as rabbits, guinea pigs, and dogs, of the great regenerative power of the pancreas, regeneration both of island tissue and the pancreatic juice producing cells and the apparent absence of such regenerative power in the pancreas of the human species, at least in those people whose pancreatic reserves have, through heredity or the accidents of living, been reduced to the point of actual diabetes. But whether we are here dealing primarily with ageing or with accidents of living, it is nevertheless a fact that, in some individuals at least, the hormone link of the pancreas may stand the wear and tear of living up to and beyond the age of 100 years in man, provided the pancreas reserves have survived or met the needs up to the age of 50 or 60.

The work of L. R. Dragstedt and associates on the second pancreas hormone or hormones (Lipocaic) as a fundamental factor in normal fat metabolism may be a more important element in the ageing processes than is insulin, for fatty degeneration or infiltration of cells and tissues (such as the blood vessels in sclerosis) seems to be an almost universal phenomenon in the ageing and the very old animal. We have no information on the requirement of lipocaic with age, or the ability of the ageing pancreas to supply this necessary factor.

Pituitary. As regards the pituitary gland, structural changes have been described in the hypophysis of old animals as well as old people, but in the absence of specific pituitary disease, this endocrine gland appears to be remarkably stable at least up to the age of 80 or 100 years. There is no evidence at present for ascribing

the early failure of the ovaries, the later failure of the testes, and the alleged atrophy and hyposecretion of the thyroid in advancing years to decreased production of the gonadotropic and the thyrotropic hormones respectively.

Adrenals. Armchair biologists have found little difficulty in pointing out the almost perfect parallel between the symptomatology of ageing and that of impaired adrenal cortical function, such as general asthenia, impaired digestion, increased pigmentation of the skin and low basal metabolic rate. Thus one might make out a plausible case for gradual adrenal-cortical failure as a causative factor in ageing. But the usual arterial hypertension with advancing age does not fit this picture, and significant adrenal cortical failure is always associated with the disturbance in the balance of the inorganic salts of the blood plasma, a phenomena which is absent in old people. There is at present no evidence that deficiency or excess in adrenal hormone production is a significant factor in ageing.

Parathyroid. The parathyroid hormone is important in the physiology of bone and in the regulation of the calcium and phosphorus of the blood. The latter is usually practically normal in the old and the very old people. The bones of the aged are not normal, but obviously we cannot ascribe the bone impairment of the aged to either hypo- or hyper- function of the parathyroid glands.

Thymus. The thymus was once classed with the endocrine glands and it may indeed have some endocrine function in the fetal and preadolescent life of man, as well as in animals below man (possibly the birds). But after adolescence or body maturity, the thymus becomes essentially a lymph gland, the findings of Rowntree and associates that injection of thymus extract induces accelerated growth and precocious sexual maturity in rats have not been substantiated, and the still earlier work indicating that the thymus may be necessary for the life of bone, if not for the life of the individual animal, was long since wiped off the board by the conclusive work of Park and McClure. Indeed the so-called "persistent" thymus was once thought to be the cause of sudden death.

Bone, Teeth, and Connective Tissue

A gradual solution and absorption of bone in old mice has been described. In man, the bones become more brittle with advancing years. This may be due to a change in the chemical combination of the bone calcium, a change towards a more amorphous state. The demineralization of bone that proceeds with advancing age does not go on with equal rate in all the bones of the body. Todd is inclined to charge the age changes in bones and connective tissue to arterial sclerosis, that is, to impaired circulation and nutrition. There is a gradual reduction in the red bone marrow in the vertebra, and decrease of the lecithin in the bone marrow with advancing years. Parallel with these structural and chemical changes in bone there is, at least in the very old, a decreased capacity of bone healing in the case of fractures.

In cartilage, atrophic and regenerative changes in advancing age tend to proceed parallel. In true tendons and ligaments, age-changes, apart from specific disease and malnutrition, have not been made out.

In the case of teeth, decreased permeability of the enamel, thickening of the secondary dentine, and increased calcium content with age have been reported. In some herbivora, an actual mechanical wearing out of the teeth from mastication occurs. Such mechanical wearing out is surely a minor factor in modern man. The decay and failure of teeth with age in modern man is probably more a matter of nutrition and other accidents of living than the rapid ticking of the hereditary time clock.

Lymphatic System

The changes in the number and kind of lymphocytes and leukocytes with age does not seem significant. These cells are individually short lived, and the tissues

producing them seem to be able to do this job adequately, at least up to the age of 90 to 100 years. Nevertheless, there is some evidence of atrophy and fatty infiltration of the lymph nodes in old animals and old people. The lymphoid tissue in the vermiform appendix decreases with age. There is some decrease in size of the tonsils and adenoids in people 50 to 80 years old, and a similar but slight decrease in the lymphoid tissue of the spleen. On the whole, both the ageing factor *per se*, as well as the accidents of living, appear to deal lightly with the lymphatic system.

The Blood

The blood of the newborn and the very old is almost as accessible to quantitative study as are the more superficial tissues of the human body, and such studies have grown apace in the last 50 years, driven not so much by the curiosity concerning ageing as the curiosity and necessity for information in relation to specific diseases. Increased fragility of the erythrocytes with age has been reported. But in the absence of specific disease, this is not sufficient to cause anemia in old age. Indeed in the entire blood system, both cell count and cell character, plasma volume and plasma composition, there is a greater uniformity in this tissue throughout the entire span of life than in any other organ of the body. It is, however, probable that all the subtle age changes in the blood of man have not been discovered, because of lack of adequate methods. It seems to be a fact that the serum of old chickens retards growth and also induces fatty degeneration in connective tissue cells in tissue cultures, in comparison with plasma from chick embryos. Nevertheless, in the absence of serious impairments in diets, in the renal, respiratory, circulatory, and endocrine mechanisms, the fundamental homeostatic mechanisms in which the blood plays such an important part (body temperature, acid base balance, blood sugar level, regulation of blood pressure and respiration) are able to meet the ordinary needs of the individual man or woman at the age of 100 and beyond. But the blood is not able to meet the extraordinary needs of excessive strain, at least not to the degree that similar physical or dietary strains are met in people of 15 to 40 years of age. This loss or diminution in the factors of safety with age, on the basis of the present knowledge, is probably to be ascribed to impairment of kidneys, lung, and circulation, and capillary permeability rather than to changes in the blood itself.

The Skin

The common changes with age in the hair, skin, and nails are familiar even to laymen. In the case of the hair on the human scalp, it is also known that acute infections, disorders of metabolism, and endocrine disorders, intensify these involutional changes. The skin changes include increased pigmentation of the exposed parts, decrease of water, decrease of fat and decrease of elasticity in the skin, as well as decrease in its growth and regenerative capacity. According to Todd, a skin wound of 40 sq cm in a person 20 years old heals on the whole in 40 days. The same size skin wound in a person 40 years old requires for healing about 80 days. At the age of 60, the same skin would require 5 times longer to heal than in a child of 10. In this regard the skin follows the descending curve of regenerative capacity with age seen practically in all the other tissues of the body. The decrease in skin elasticity appears to run parallel with the actual degeneration of the elastic connective tissue fibers. The decrease in the subcutaneous fat may play a minor role. The dryness of the aged skin is probably secondary to decreased secretion of the sebaceous glands, although these glands show, on the whole, hyperplasia with the advancing years.

On account of its cosmetic significance for modern man, the failure of color and the gradual falling out of the hair of the scalp has received a great deal of unscientific attention. There are indications of an actual hereditary factor. Diet, disease, and vascularity, unquestionably play a role, but in the absence or with the minimum

of these factors at play, there seems no doubt that the hair on the scalp at least would sooner or later run its course of graying and death, considerably before the zero hour of the time clock for the individual person. The complexity and the individuality of some of these mechanisms, hereditary and accidental, are indicated by the fact that parallel with the graying and falling out of the hair on the scalp, some of the body hairs, such as eyebrows, the hair in the nose, and on the external ear, may show an increased growth if not an increased pigmentation with the lengthening shadows of the accumulated years.

Except for immunities to specific infection and the pathological hyperplasias and tumors, all the changes in the machinery of the body which parallel, and, in fact, constitute the ageing process point to a gradual depletion of the hereditary tissue reserves or "factors of safety," *so that the ageing individual becomes gradually less able to meet the usual accidents and the unusual stresses of living.* As long as these can be avoided life goes on until the corroded life links break, even in the absence of specific storm and stress. But this way out appears to be very exceptional even in our own species.

Diet and Life Span

Since the scientific information on the kinds and the quantity of foods required for growth and health is very recent, considering the history of the human race, and that this information is still fragmentary, it is evident that in the past man's diet, both as to kind and quantity, was determined by appetite, hunger, and the availability of the foods. We may therefore assume that underconsumption and excess consumption of foods, starvation and gluttony, emaciation and obesity, are phenomena as ancient as man himself.

Life insurance statistics show clearly that underweight as well as obesity tend to shorten the life span of man. McCay finds that on a diet adequate in quality, but inadequate in amount fed so that growth of the animal is practically at a standstill, the life span of rats is significantly prolonged. In this experiment the control group of rats was fed the same kind of food ad libitum, so that this group may have had its life span shortened by excess eating, that is, by obesity. It is well established that many, if not all, persons showing marked and persistent underweight or emaciation have functional disorders interfering with the digestion, absorption, or the metabolism of food stuffs, excess metabolic rate, or chronic disturbance of appetite and hunger (anorexia nervosa). That such persons die prematurely presents no particular problem, since we have here clearly an excess corrosion of essential links in the life chain. But why does the overweight person, the obese person, who seems otherwise healthy, die prematurely? This is a fundamental problem in geriatric medicine, for in the absence of specific disease, overweight or obesity tend to increase in men and women past 40 years of life. Is obesity itself a disorder, a disease? (Also, consideration must be given to direct mechanical interference with respiration and circulation by crowding of intra-abdominal contents against diaphragm.) Or is the shortening of the life span merely a consequence of obesity as implied in the popular saying that "fat people dig their graves with their teeth?" Admitted that there may be hereditary factors in some species, such as the whale and the hog, favoring deposition, or excess deposition of body fat, it is nevertheless true that all animals, otherwise normal, can be fattened by eating in excess of the expenditure of energy. In man obesity is the result of the same fundamental cause, that is, eating in excess of the energy expended. The work of Newburgh goes to show that intake of food below the energy requirements reduces body weight in all types of obese people.

During the last twenty-five years considerable, though superficial, attention has been given to the possible relation of thyroid, gonad, and pituitary disorders to human and animal obesity. It now seems established, or at least highly probable,

that there is no such thing as a primary endocrine obesity, apart from endocrine influences on appetite, hunger, and physical activity. The marked obesity that may follow destructive injuries at the base of the hypothalamus seems to be largely due to increased food consumption because of increased appetite. Endocrine therapy of obesity has been disappointing, except in the case of thyroid extract, and the latter has to be administered to the point of inducing the initial symptoms of the disease, thyroid toxicosis, before weight reduction is secured, in absence of reduced food intake. On the basis of present information it seems likely that the development of obesity in some people past 40 years of age is primarily due to these people persisting in excessive eating and the satisfying of specific appetite for foods, when the rate of tissue oxidation and general physical activity are both on the decline.

It is not difficult to understand why ingestion of food to the point of obesity is injurious to people with reduced factors of safety in the matters of insulin, pancreas, sugar, and fat metabolism. Such dietary excesses damage by overwork an already impaired mechanism. But in the absence of diabetes, actual or incipient, why does obesity, maintained for years, initiate or aggravate cardiovascular, renal, and other disorders that shorten the life span? While the answer to these questions is being sought by experiments and accurate observation on mice and men, the prevention of obesity in all people past 30 appears to be a prophylactic imperative, a must, in gerontology. And as a general proposition, it is safer for the patient to do this by reducing the diet than by taking toxic drugs.

An extensive bibliography, including the most significant original investigations, is to be found in the author's book "The Problems of Ageing," 2nd revised edition, Williams & Wilkins Co., Baltimore, Md., 1942.

The Formation of Concretions

L. LICHTWITZ †

Concretions found in man and animals are inanimate structures, the majority spherical or egg-shaped, with a consistency varying from stony-hard to soft-elastic. They also vary in many other qualities and particularly in constituent material, but they have in common two dominant characteristics: an albuminous substance and a concentric structure.

Biliary and urinary calculi are best known to physician and laymen. They are considered to be pathologic in character; but harboring such concretions is not at all identical with disease. They are often harmless, more so in the biliary system than in the urinary tract, and if they do not cause any signs and symptoms they become known as incidental findings on x-ray examination and on necropsy. They are, however, potential trouble makers and certainly do not serve any useful purpose.

This latter statement, however, cannot be generalized. There are concrements, physiologic in character, universally present in the animal kingdom and of great functional importance. I here refer to the otoliths which in most instances are produced within the internal ear, while some species of fish (torpedo *Akanthias*) pick up sand or gravel to serve as equilibrium-maintaining apparatus. Otoliths, as far as chemical composition and architecture are concerned, do not differ from urinary calcium carbonate calculi. It can be assumed with a great degree of safety that both these concretions are produced by the same process. Following the formation

† The Editor regrets to state that Dr. Leopold Lichtwitz died on March 18, 1943. Following an eminent career in Germany he had served Columbia University for eight years as Professor of Clinical Medicine. His passing is a loss to this country and to science. J. A.

of otoliths we learn to know the physiological process, which may well be the general mechanism for the development of concretions.

In the trout and in the chicken embryo, which have been subjects of such studies, there appears in the endolymph of the auditory vesicle a protein coagulate adhering to the sensory epithelium. This coagulate grows by apposition of a number of concentric layers, thus producing a soft concretion, in which, during a limited period of the embryonic development, lime salts are deposited.

This sequence of events shows clearly the way of nature in producing concretions, namely the formation of a colloid structure, which becomes incrustated by substances of low solubility. In a rather large number of physiological instances the second step does not occur. This leads to soft bodies of concentric structure, as found in the thymus (Hassal bodies), in the prostate, in the central nervous system (corpora amylacea) and in other organs. The same structure is characteristic for starch and is met with throughout nature.

Soft concretions of pathological character are known to occur in the pelvis of the kidney and more rarely in the gallbladder. These "stones" consist of concentric layers of albuminous material around a protein coagulate (Figure 1) or any other

FIGURE 1. Protein Concretion, two millimeters in diameter. Three such concretions were found in a case of pyelocystitis.

nucleus. The protein sometimes shows fibrin staining and occasionally the phenomena characteristic of amyloid. In other instances in these concretions, bacteria and degenerate cellular material are recognizable. Obviously, part of the protein substances forming this type of concretions do not represent normal urinary constituents.

The importance of the colloid coagulate for stone formation, calcification and other incrustations, was first recognized by H. Meckel von Hemsbach, who in his famous but little read treatise "Mikrogeologie" (1856), made the statement that two factors

are essential for the production of calculi: First, an organic compound of mucus character, in which insoluble or poorly soluble material can be deposited, and second, a fluid super-saturated with petrifying or incrusting substances. Meckel continues by saying that the formation of stones depends exclusively upon the incrustation of an organic substrate by precipitable material.

Considering that at this time, almost eighty years ago, there was no colloid chemistry, Meckel's conception represents an amazing case of prescience. Of course, his ideas were not heeded and were almost forgotten, and it took a long time before we reached his point of view. Since we are equipped with more information in the basic sciences, we are able to clarify the mystery of stone formation.

Three physico-chemical principles participate in this process: the laws ruling the behavior of colloids, the laws of surface activity and the laws of solubility and supersaturation.

The body fluids (particularly bile and urine) represent complicated systems, in that substances, electrolytes as well as non-electrolytes, are kept dissolved in higher concentrations than corresponds with their solubility in water. There are a number of factors by which a well stabilized supersaturation is maintained, the most important one being the presence of colloid material. These colloids give protection against precipitation of substances in supersaturated solution, as long as their degree of dispersity is sufficient.

The stability of the colloids, here as elsewhere, is limited. This is easily observed in the urine where, shortly after evacuation, a mucus-like coagulate appears, the nubecula (Figure 2). This phenomenon is specific for acid urine, while in alkaline urine a different, ether-soluble colloid is present, which coagulates on the surface. Here it forms a membrane glittering with interference colors, like fuel oil on the surface of water (Figure 3).

When the urine is deprived of the protecting principle by these or other means of colloid coagulation, sediments appear, *e.g.*, urates, calcium oxalate, phosphate and carbonate of calcium and magnesium. In the bile where the same principle is active, bilirubin calcium and cholesterol are the most frequent sediments.

Sediments, crystalline as well as amorphous, contain colloid material which represents an impurity but has a definite influence on the crystal form.⁴

The nature of sediments and the mechanism of their formation may be left out of consideration, because their relationship to the genesis of concretions is very limited. It is extremely rare that crystals agglomerate to form a small body which, since it has neither concentric nor radial structure, resembles rubble or a heap of paving stones. Crystals may grow within the urinary tract to the size of sand. This "gravel," commonly consisting of uric acid, may bring on slight discomfort, such as burning on urination.

In most cases, sediments are evacuated readily and rapidly. When they are not, they may form nuclei around which concretions are formed.

The presence of a nucleus or of nuclei is essential for stone production. The nature of the nucleus is of no significance. Besides sediments, coagulates of blood, fibrin, cellular detritus, casts, agglutinated bacteria, foreign bodies of any description may serve as nuclei. Obviously, this variety of particles has nothing in common chemically. It can be safely assumed that their ability to act as nuclei is a matter of surface activity. Coagulable colloids become absorbed on the surface, forming layers, which in the majority of instances become incrustated by such substances which are present in super-saturated solution.

Activity, and inactivity as well, play an important rôle in biology. The stability of the fibrinogen in blood plasma depends upon the integrity of the vascular endothelium and its surface inactivity. Injury of these linings is followed by agglutination of thrombocytes and thrombus formation. The same principle seems to prevail in the biliary and urinary tracts. Very little attention has been paid to the physical

relationship between body fluids and the epithelial linings of channels and cavities. As far as urine is concerned it seems that there is no adhesion between urine and the epithelial layer of the urinary tract. Adhesion within the renal tubules would greatly interfere with the flow through these channels. It well may be that there is a physical contact, similar to the relationship between mercury and glass.

FIGURE 2. Nubecula with deposits of salts. (C. Posner)

This indifference between fluid and linings may change by alteration of the surface, as well as by variation of the fluid. Both these processes are most common. The appearance of an increased quantity of colloid material in the urine, as in the case of albuminuria and colloiduria, enhances the chance of precipitation, while even a slight alteration of the epithelial layer leads to actual colloid coagulation.

This is best evidenced by the formation of casts, which are due both to the presence of coagulable material in the kidney and to the loss of smoothness or surface indifference on the part of the renal epithelium.

FIGURE 3. Calcified colloid precipitate on the surface of an alkaline urine.

Two important discoveries point to the effectiveness of this very mechanism in the process of stone formation.

The one is the appearance of concretions in the pelvis of the kidney, urinary bladder, and biliary tract, as sequela of vitamin A deficiency. Lack of A, the epithelium-protecting vitamin, leads to a deterioration of epithelial cells and eventually to keratinization. In this condition nothing is known of changes in the composition of the fluids, while the pathology of the wall undoubtedly involves a profound alteration of the surface.

The second fact is the appearance of kidney stones in hyperparathyroidism, that is, in hypersecretion of parathyroid hormone or in super-response to physiological production of this compound.

Parathyroid hormone represents the tool by which the metabolism of the skeleton is controlled and its dissimilatory phase is brought about. Hyperparathyroidism may lead to decalcification of bones, hypercalcemia and increased output of calcium. This has led, rather invitingly, to the widely accepted doctrine that kidney stones, which in this condition consist of phosphate and carbonate of alkaline earths, are due to augmented urinary calcium. We will see later that the concentration of compounds which petrify concretions, have almost no bearing on their formation. In addition, hyperparathyroidism brings about stone formation without any involvement of bones and without any calcium mobilization. It is due to the fact that this hormone exerts a very powerful influence upon the kidneys. It is a strong diuretic and when it acts for a considerable time produces chronic nephritis. A group of individuals respond more readily with the kidneys than with the skeleton, and develop kidney stones without the bones being affected, or before they are affected.

The mechanism of its action is elucidated by the influence of the parathyroid hormone on protoplasmic structures. This hormone is a potential poison for cells and fibers; it produces necroses in various tissues, such as the heart muscle, the medial coats of the smaller arteries, the gastrointestinal tract, the walls of the bronchi, the alveoli of the lungs and subcutaneous tissue. These lesions readily become calcified, according to the rule that calcification generally follows coagulation and the loss of colloid protection. The kidneys participate in hyperparathyroidism not only by appearance of stones in the kidney pelvis, but also by lime deposits in the lumina of the proximal tubules and in the kidney substance proper. There is scarcely any doubt that here also degeneration precedes calcification, and that alteration of the epithelial surface is part of the process.

Thus, the mechanism of parathyroid hormone in stone formation is of the same nature as the effect of A avitaminosis, with the difference that in hyperparathyroidism the biliary tract is spared, the hormone having no influence upon its structures.

The alteration of the epithelial surfaces from loss of smoothness and surface inactivity to outright necrosis, with, as well as without calcification, brings about colloid-precipitation and makes sediment stick to the lining, thus preventing its evacuation. In this way a potential stone nucleus is produced. Quite often necrotic plaques, particularly when calcified, act as nuclei. In both cases the growing concretion will be primarily adherent, and may become disengaged at a time when it is too big to pass the ureter without difficulty, if at all.

Processes of this kind occur also in the tissue below the epithelium of the renal pyramids. In this area deposition of uric acid takes place during early infancy (the uric acid infarct) and also later in life in gout. The "calcium infarct" of the pyramids, first described by Jacob Henle (1809-1885) is a quite common phenomenon in all periods of life, its incidence increasing with ageing. These calcium deposits converge on the top of the papilla, where they protrude, rendering the surface rough and grinder-like (O. Lubarsch). In recent years it has been shown by A. Randall that these calcium infarcts exert pressure on the covering epithelium, which eventually disappears, leaving the calcified plaque as carrier of an active surface and as

potential nucleus in free contact with the urine. In a series of excellent investigations Randall has demonstrated the development from the subepithelial calcium infarct to a small calculus attached to the pyramidal wall.

This formation of nuclei within the wall and their migration into the cavity, in all probability plays a great rôle in the development of urinary calculi. It also happens in the biliary system though here it is of minor practical consequence. In the case of the so-called strawberry-gallbladder (that is, infiltration of the wall by cholesterolesters) we have found minute cholesterol concretions attached to the epithelium (Figure 4). Commonly gallbladder stones form around nuclei, which origi-

FIGURE 4. Strawberry gallbladder. Small cholesterol concretions are attached to the epithelial lining.

nate from the bile proper. Decomposition of the colloid system of the bile is brought on by a number of factors, such as albuminocholia, pH, diminution of bile acid concentration by destruction or absorption, possibly also by heavy metals, and leads to the precipitation of bilirubin calcium and albumen. By this process the bile becomes the consistency of a coarse gruel and forms a black-greenish mass of small particles (Figure 5). These are the common nuclei; they are found in the vast majority of gallstones when their transformation is not too far advanced. In a small number of cases the nuclei originate in the intrahepatic bile ducts and migrate into the gallbladder. These intrahepatic stones are amorphous conglomerates of bile pigment and calcium, completely or almost free of cholesterol with a remarkable great content of heavy metals, particularly of copper. In another small minority, foreign bodies, such as parasites and eggs of parasites, serve as nuclei.

To grow to a concretion the nucleus must remain in the cavity. A floating nucleus has a very poor chance in the urinary tract when the flow of urine is not obstructed. It is different in the gallbladder, which represents a receptacle, which in a number of cases, increasing with ageing, is not capable of complete emptying.

FIGURE 5. Coagulated bile, gruel-like in consistency. The black particles consisting of bile-pigment, calcium and protein, represent potential nuclei.

In these instances there is a dead space, in which residual bile may produce nuclei.

It is a remarkable fact that as a rule in more than 90 percent of the cases, formation of gallstones takes place but once. This is borne out by the fact that the common gallstones (be there three, four or any number up to a few thousand in the gall-bladder) represent one generation. The stones are equal in every detail with the exception of the size, which depends upon the size of the nucleus (Figure 6) or is

FIGURE 6. Family of common gallstones. The size depends upon the size of the nuclei.

caused by conglomeration of a number of original stones. There are a few exceptions, in which two and even three generations of gallstones are present. A second generation is bound to appear, when a gallstone is broken. The fragments act as nuclei; they possess the same specific gravity as the whole stones and herd with them in this particular part of the bladder cavity which we designated as the non-evacuable

or dead space. In this space the concretions are fairly safe. Compared with the tremendous number of stone-carrying gallbladders (in European countries stones are found on necropsy in about twelve percent of the cases; this, if valid generally, would account for about 18,000,000 cases in the United States), stones leave the bladder to enter the cystic duct or to pass the common duct in but a very small number of instances.

The recognition of the fact that practically all gallstones found in a gallbladder are produced simultaneously and that this happens only once, leads to the conclusion that the presence of gallstones prevents the formation of new gallstones.

Resting securely in the gallbladder, the young concretions seem to have plenty of time to develop and grow. However, the time required for final development is surprisingly short; x-ray and other types of examination indicate that two weeks may suffice. It may be a matter of days and even of hours, until the final size and shape are determined. As a matter of fact, a biliary calculus in the stage of formation cannot be found, either at operation or on necropsy. Precipitation of colloids is probably as rapidly accomplished as the clotting of blood. As is known from studies on calcification, and particularly on mercury poisoning, calcium incrustation is discernible after a few hours.

Very soon after its inception the concretion stops growing. Its smooth and polished surface is inactive and apposition of new layers does not take place any longer. Stones evacuated after an interval of years are absolutely unchanged in size.

The kidney pelvis is no receptacle and stone formation takes place regardless of the presence of stones. Here also the growth of stones, is often limited, particularly in the absence of infection. In a number of instances the stone grows to and beyond the capacity of the cavity, filling the calices and destroying the renal parenchyma (Figures 7 and 8). The time of final development of smaller stones is just as short as with the common variety of gallstones.

Two factors have been emphasized as of importance and even as essential for formation of concretions, stasis and infection. The non-evacuatable space of the gallbladder can be considered as equivalent to stasis. Generally, however, stasis is of significance only in that it facilitates infection. Infection leads to damage of the epithelial linings, to the appearance of a larger quantity of colloid material in dissolved and coagulated form, to agglutination of bacteria; in the urine to fermentation of urea leading to ammonia production and alkaline reaction, in the bile to destruction of bile acids and this facilitates stone formation. In the majority of cases, however, in both bile as well as urine, concretions originate in the absence of any infection.

When a nucleus is present, colloid layers are rapidly formed and thus the concentric structure of the concretion is established. When, as is usually the case, this soft primary concretion permits diffusion, electrolytes migrate and are precipitated when their concentration in the fluid is greater than aqueous saturation, and when the colloid layers lack in colloid protective capacity. There are almost no pure urinary stones. The petrifying material may vary in different layers. The urinary concentration of electrolytes above the point of saturation is of negligible influence. The electrolytes invariably crystallize but never in those forms which they show in the urinary sediment. They crystallize in radial direction, thus producing the radial architecture of the concretion. By dissolving the crystals the radiating design disappears, while the colloid concentric layers remain.

It has been assumed (H. Schade*) that the concentric architecture is brought about by alternating deposition of colloid and crystalloid. There is no evidence and very little probability that concretions are made like a layer cake. It is certain that urinary sediments do not participate in the development and hardening of stones.

The concentric pattern which characterizes the cross section is only to a small

part due to the apposition of colloid layers, the majority representing *Liesegang rings*.

This interesting phenomenon, which can easily be reproduced in a test tube (Figure 9) or on a gelatine film (Figure 10), is evidence that substances which form the

FIGURE 9. Liesegang rings produced in a test-tube.

FIGURE 10. Liesegang rings produced on a gelatine film.

nucleus of the stone, are continuously dissolved, diffuse through the concretion, and are repeatedly precipitated in its colloid medium (Figure 11). This will be shown in gallstones where the development can be traced through all its stages.

The stone, even after having reached its final shape and size, undergoes a metamorphosis.

The vast majority of gallstones are not spheroidal. Multiple stones start in globular shape but are rapidly transformed to tetrahedral and hexahedral forms, that is, those forms which have the largest surface in relation to their mass. B. Naunyn and V. Goldschmidt have analyzed this process. Two young concretions, still soft but having their final size, become attached to one another. The tangential

FIGURE 11. Kidney Stone. Calcium Oxalate grown around a blood coagulum which by desiccation and contraction has transformed the concretion to a hollow body. The picture shows a part of the shell with a few layers and many Liesegang rings. Residues of the blood coagulum are visible on the interior surface.

FIGURE 12. Family of four young biliary calculi. The nuclei are still present. The body shows fan-like cholesterol crystallization. The cortex consists of three layers with very little evidence of pigment migration.

FIGURE 13. Common gallstone. The nucleus has completely emigrated. There is the typical triangular space in the center. The body shows fan-like cholesterol crystallization between the crystalline rays. Liesegang rings are in the cortical layers.

FIGURE 14. Common gallstone. The triangular space in the center is filled with amorphous cholesterol.

point of contact widens to a circle of adhesion, from the periphery of which the profile rises in angles of 60 degrees or 90 degrees. Simultaneously, by loss of water, contraction takes place, to which the surface responds with transition to polyedral forms. The nucleus, initially semi-fluid (Figure 12), disappears, rendering the center of the concrement a hollow space of a characteristic triangular shape on cross section (Figure 13). In this stage of development the cholesterol in the peripheral part of the nucleus has started crystallizing in a fan-like radial pattern with dark-brown pigment squeezed between the crystalline rays. The ground-substance of the concretion and the surface, despite its inactivity as far as absorption is concerned, still are gel-like and permit diffusion. Cholesterol fills the central hollow space first in amorphous form (Figure 14) but soon crystallizes (Figure 15). Simul-

FIGURE 15. Common gallstone. The cholesterol immigrated into the center has crystallized.
(Pseudo-nucleus—B. Naunyn)

taneously bilirubin calcium, which first has formed the nucleus, later surrounded the empty space migrates and on its way out is precipitated in the colloid layers in series of Liesegang rings, thus contributing largely to the colorful pattern of the cross section. Migration of cholesterol inwardly and bile pigment outwardly depends upon the gel character of the ground substance. When by ageing or by circumstances of unknown nature the substance becomes rigid and impermeable, the metamorphosis ceases and the composition and structure of the concretion becomes fixed.

In a smaller number of cases only one nucleus is present and only one concretion

develops. A solitary stone maintains its original globular or ellipsoid shape. Thus, throughout its substance intraconcremental pressure, diffusion and migration are evenly distributed. There are no vectors and sectors, no corners and edges, no formation of a central cavity. The surface, uninfluenced by a change in shape, maintains a wax-like appearance.

In any other respect the solitaire undergoes the same metamorphoses as the common stone but often proceeding further, probably due to the quality of the surface. The pigment in many instances disappears completely; cholesterol may fill the stone to capacity and, on crystallizing, reduce the ground substance to such a degree, that no concentric pattern remains. When the metamorphosis of a solitaire has advanced thus far, it is not possible to recognize the course of the development. There are, however, many specimens in which rigid crystallization arrests the migration of pigment in various stages. Then nucleus substance and Liesegang rings remain permanently (Figures 16 and 17). This is particularly evident in Figure 18, show-

FIGURE 16. Cholesterol solitaire with large nucleus and Liesegang rings.

ing a stone with exhausted nucleus and two rings trapped in the periphery by crystallization. In the stone shown in Figure 19 the nucleus has disappeared and the radial cholesterol crystals have pierced the rings and transformed them into dotted circles.

The course of development is clearly visible in solitaires of ellipsoid shape. In these the crystallization of cholesterol, which has migrated into the apposition layers, starts (we do not know how), in the centre, thus developing a globular cholesterol solitaire within the primary concretion. The layers remain recognizable in the periphery and particularly at the poles, thus revealing the original concentric structure (Figure 20). In instances, rare but definitely demonstrating the inward mi-

gration of cholesterol, the primary stone of concentric structure is divided into two parts which crown the cholesterol solitaire in perfect symmetry (Figure 21). In other instances intraconcremental growth of a cholesterol solitaire leads to the stretching of the original stone, as may be seen from the course of the layers and Liesegang rings in Figure 22.

It has been claimed, particularly by L. Aschoff, that common stones and solitaires differ in etiology, in that pure cholesterol stones originate in a non-inflammatory

FIGURE 17. Cholesterol solitaire with Liesegang rings.

FIGURE 18. Cholesterol solitaire showing a small residue of nuclear pigment, complete radial crystallization and in the periphery two Liesegang rings.

manner from a faulty cholesterol metabolism, while the common stones are products of an inflammatory or infectious biliary process.

This statement, pathetically erroneous, has entered textbooks, where it will persist for a long time. Whatever "faulty cholesterol metabolism" may mean, it is certain that the cholesterol content of the bile does not depend upon cholesterolemia

FIGURE 19. Cholesterol solitaire. The nucleus has disappeared. Liesegang rings are pierced by cholesterol crystals and thus transformed into dotted circles.

FIGURE 20. Ellipsoid solitaire of concentric pattern. A nucleus is not visible and certainly not present in the original form. A globe-shaped cholesterol concretion has developed in the center. (R. Brühl)

and cholesterol intake, and that the formation of gallstones is not favored by hypercholesterolemia. Liver bile is poor in cholesterol; in man it averages between 60 and 160 mgm percent. This variation in concentration is insignificant compared with the rise occurring in the gallbladder as a result of its concentrating capacity. This concentrated bile normally represents a well stabilized system. It does occasionally develop a deposit of cholesterol in the form of a few characteristic crystalline plates or of double-refractory droplets. Precipitates of this kind, as a rule, cannot be found in any sort of gallstones and do not act as nuclei. Cholesterol does not play a leading rôle in the formation of biliary concretions; it enters the stones secondarily, its mass increasing with advancing metamorphosis. Then, by its quantity and by its obtrusive physical and chemical qualities, it represents an important and impressive part of the concretion.

FIGURE 21. Stretched stone. A radial cholesterol concretion has developed within a solitaire of concentric pattern, consisting chiefly of ground substance and bile pigment calcium. By the intrusion of the cholesterol concretion the original stone is stretched, the two separated parts crowning the central stone in perfect symmetry.

FIGURE 22. Stretched Stone. A radial cholesterol concretion grown within a gallstone of concentric pattern. (B. Naunyn)

It has been emphasized that a ball-shaped biliary concrement can develop only when there is but one nucleus. In this case, exclusively, the conditions for complete cholesterization and radial crystallization are established. The truth of this statement is borne out by a specimen, in which a radial cholesterol stone developed around the fragment of a common stone as nucleus (Figure 23). In this gallbladder a number of unsevered common stones were present. These, however, due to their solid and inactive surface, could not and did not interfere with the formation of the

FIGURE 23. Combination stone. Around a fragment of a common gallstone as nucleus, a radial pure cholesterol concretion has formed. Within the fragment the disintegrating process, which has led to fragmentation, continues.

new specimen, which developed according to the processes governing the genesis of a solitaire.

This concretion belongs to a group of gallstones, which have been designated as *combination stones*.

It has been mentioned that the growth of the solitaire is limited. Growth being due to apposition of layers on the surface, it can be assumed that the termination of growth follows the loss of surface activity. The surface of solitaires is inactive to the constituents of normal bile. When, however, by a pathological process, such as infection, cholecystitis or albuminocholia, the bile is rich in precipitable colloids, new apposition of layers may take place around the old solitaire. Then a combination stone arises. In the beginning the new shell shows distinctly concentric layers (Figure 24), pigment and Liesegang rings. Later cholesterolization and crystallization

FIGURE 24. Combination stone. Around a cholesterol solitaire with well-preserved (trapped) nucleus, a shell has formed. The shell shows a concentric pattern, in parts eliminated by cholesterol crystallization.

proceed, starting from the crystal rays of the central stone and advancing throughout the shell, eventually to the final pattern characteristic of the mature cholesterol solitaire (Figure 25).

FIGURE 25. Combination stones. LEFT: The shell, incompletely cholesterized, still shows the concentric pattern. RIGHT: The cholesterolization of the shell is complete.

Another type of gallstone is represented by the barrel-shaped stones (Figure 26).

FIGURE 26. Three large stones filling the gallbladder to capacity. The largest stone is barrel-shaped. Between the stones are articulation-like surfaces.

They are the largest concretions, often filling the gallbladder to capacity. Little is known about the early phases of their development. It may be that in a cholecystitis the bile filling the bladder coagulates en masse and becomes a giant stone or a system of two or three stones, which are in contact by articulation-like surfaces. They undergo in principle the same metamorphosis as the other types of concretions. Their architecture is influenced by pressure from the outside (the gallbladder wall) and by the fact that the interconcremental surfaces are exposed to greater resistance and less open to cholesterol migration. It can often be seen that the surface of the stone

in contact with the gallbladder wall is covered with cholesterol, which seems to originate from epithelial cells and leucocytes.

In a small number of cases the gallbladder contains calcium carbonate stones or bilirubin calcium stones. The latter, very hard in consistency and cholesterol-free, develop more often in the extrahepatic bile ducts, particularly in the common duct.

A great problem is the dissolution of biliary and urinary calculi. There is disintegration leading to fragmentation and formation of cavities and holes. Nothing is known of the character of this process. There is more probability that it is peptisation than chemical dissolution. Generally concretions are more stable than patients. Chemical solution of petrifying material would leave the colloid shadow behind. When a stone is broken up the fragments remain. Shadow and fragments represent nuclei around which new stones will readily be formed.

Aero-emphysema and Caisson Disease, a Problem of Colloid Chemistry *

JEAN PICCARD

Professor of Aeronautical Engineering at the University
of Minnesota, Minneapolis

Caisson Disease and Supersaturation

It is known that under certain conditions an excess of nitrogen dissolved in the blood or in other parts of the body will coalesce to form bubbles. These nitrogen bubbles are harmful or even fatal to man. To prevent the phenomenon we must understand it. The problem itself is old and well-known to deep-sea divers, but it is equally important in aeronautics. Since aerial battles are fought today at ever-increasing altitudes, the problem is becoming more and more acute.†

* We wish to express our appreciation to the publishers of the *Proceedings of the Staff Meetings of the Mayo Clinic* for permission to use in this article tables and excerpts from "Aero-emphysema and the Birth of Gas Bubbles" by Jean Piccard, *Proceedings*, **16**, 700-704 (October 29, 1941).

† In the case of too rapid decompression, divers and caisson workers are afflicted by what is called *caisson disease* or *diver's palsy*. An analogous affliction suffered by the aviator after rapid ascents is called *aero-emphysema*. The word *bends* is used in both cases, especially for less severe cases of the affliction. The word *emphysema* by itself means

When a diver ascends rapidly from great depth without special precautions, nitrogen dissolved in his body is liberated. The bubbles formed by this "cavitation" or effervescence, if carried along in the blood stream, will enter the capillaries, clog them and thus obstruct normal circulation. The damage done if cavitation occurs in parts of the body other than the blood is less well understood. It is certain, however, that most cases of "bends" are due to cavitation outside the blood vessels. The result in any case is skin itching, pain, paralysis or death, depending on the magnitude of the effect and on the location of the obstructions. Since a certain *supersaturation* is essential to initiate cavitation, and since any excess of nitrogen is rapidly liberated by the action of the lungs, the disease does not appear unless the decompression ratio has reached a certain value. This minimum value is about two to one, *i.e.*, it is reached if the diver, starting from any given depth, ascends to any level where the absolute pressure (atmosphere plus sea) has dropped to one-half its original value. The question of supersaturation seems to be most important in the description and explanation of aero-emphysema. Theory shows indeed that any bubble forming in water or in any other liquid must first pass through a stage in which it is too small to be stable. The whole phenomenon of supersaturation hinges on this fact: A very small air bubble in water is under such a pressure (produced by surface tension) that its content will go into solution even though the solution is already supersaturated.

The same phenomenon holds true, *mutatis mutandis*, for the formation of a droplet in air. A very small water droplet is under such a high capillary pressure: its molecules will be forced into the atmosphere and the droplet will collapse. Although the surrounding air is fully saturated or even supersaturated with water, this explains why atmospheric air is quite frequently supersaturated. Supersaturated solutions of air in water and supersaturated dispersions of water in air have an analogy with unstable colloidal dispersions of solids or liquids in water. In ordinary colloidal solutions the dispersed phase, if precipitated, comes out in a "flocculent" form. The same holds true of water-in-air as well as of air-in-water dispersions. In both cases an unstable dispersion may be maintained for a certain length of time and may then suddenly "break" for no apparent reason with the onset of precipitation. There seems to be something mysterious about this unstable equilibrium and its sudden breaking. Perhaps this is as far as the analogy with ordinary and better known colloidal solutions goes. Perhaps there is a deeper analogy which will some day become apparent.

We shall, in the following pages, discuss more specifically the breaking of the equilibrium existing in supersaturated solutions of gas in water. First, however, we shall draw some comparisons between the "birth of a fog droplet" in free air and the "birth of an air bubble" in aqueous solution.

There is one very great difference between the two phenomena. If air contains ultramicroscopic droplets of dilute sulfuric acid originating, *e.g.*, from the sulfur contained in coal, or minute crystals of sodium chloride or droplets of sodium chloride solution from sea water spray, these particles or droplets will act as *nuclei* for larger fog droplets. Nuclei are, of course, likewise under a great capillary pressure, but due to their osmotic pressure and correspondingly small vapor pressure, they do not disappear under conditions which would cause water droplets of the same diameter to vanish. This persistence is especially true for sulfuric acid nuclei because sulfuric acid, if concentrated or slightly diluted, has no appreciable vapor pressure. Nuclei in water, analogous to water droplets in air would be formed by minute bubbles of any insoluble gas. The *difference* between the two phenomena lies in the fact

"puffing or inflation of the tissue by air or gas." *Embolism* means occlusion (usually of a blood vessel) and *aero-embolism* means occlusion by an air bubble. See Paul Bert: "La Pression Barométrique" (1878). J. S. Haldane and J. G. Priestley: "Respiration" (1935) and H. G. Armstrong, U. S. A.: "Principles and Practice of Aviation Medicine" (1939).

that while there are many *liquids* of exceedingly low vapor pressure there are no insoluble gases. A glance at a table of solubility of gases shows indeed that there are no gases whose insolubility in water could be compared with the non-volatility of sulfuric acid. *Persistent gaseous nuclei are, therefore, entirely out of the question.*

An analogy between formation of bubbles and formation of droplets is that in both cases solid insoluble objects, like minute sand grains, may act as nuclei.

In supersaturated air a small amount of water may collect on a surface with relatively large radius of curvature, and this water plaque will then be stable in an atmosphere where an equal amount of water, if in the form of spherical droplets with smaller radius of curvature, would not be stable. Solids which are easily wetted (hydrophilic solids) will, therefore, produce better nuclei than hydrophobic solids. There is little question that particles of rubber or paraffin will give less efficient nuclei for fog formation than equally small particles of quartz sand, although both are insoluble in water and cannot produce hygroscopic solutions. Modern meteorology has, however, largely discounted the importance of solids as nuclei; salts or acid nuclei are much more potent than ordinary (insoluble) dust particles. Ionized molecules act also as nuclei. They need, however, in order to grow a much greater supersaturation than salts or acids.

What then will be the effect of solids in an aqueous solution? Will they be able to produce cavitation where otherwise it would not occur? There are no "aerophilic" solids in the same sense that there are hydrophilic solids. It is well known, of course, that a grain of porous clay will start cavitation and ebullition, if thrown into superheated water. This, however, does not mean much, because porous clay contains air pockets which act as nuclei, instead of the silicate itself. Wet tissue as found in the human body will never act like dry porous clay. Even porous clay, if thoroughly wetted by being boiled out and allowed to remain in water below the boiling point, loses all activity. Objects better comparable to hydrophilic units are grains of platinum or palladium. Superheated water starts boiling when a minute particle of one of these metals is dropped into it. These metals, however, absorb gases and they do not act differently, in principle, from porous clay. Base metals, on the other hand, may start cavitation in superheated water, because they produce minute particles of hydrogen under a local pressure sufficient to form hydrogen bubbles, and these, once formed, will act as nuclei.

All these cases of solid nuclei in water can be demonstrated *in vitro*, but always under conditions which are unimaginable *in vivo*.

It is quite possible that a bubble produced in human blood will start on a blood corpuscle. It may be that a white corpuscle is more active for this purpose than a red one, or *vice versa*. However, the cavitation will not start as a flat surface on the solid, but as a more or less rounded bubble. We may, therefore, assume that as a whole, cavitation in human tissue is not produced mainly by solids. Only if supersaturation is such that cavitation impends, may solids present in the human body be of importance for nuclei formation. A piece of raw meat, for instance, has very little effect, if any, on superheating of water.

If solids play a restricted role in cavitation, we can assume *a fortiori* that colloidal particles in the physiological fluids play a very small role in bubble formation in the human body.

In What Body Fluids Does Cavitation Occur?

It was originally assumed that caisson disease was produced by bubble formation in the blood and that the damage done was due to clogging of the capillaries (aero-embolism). There are specific cases reported where air bubbles have been seen in human blood *in vivo*. In other cases bubbles have been seen in other fluids and tissues, in the spinal fluid or in the eyes of living animals subjected to rapid decompression. A few years of the medical study of modern aviation have done more to

cast light on the problems of aero-emphysema than a hundred years of deep-sea diving.

The complete (double) circulation of the blood in the human body takes about 20 seconds.* Every time the blood passes through the lungs, which have a surface of about 85 square meters, it is thoroughly aerated and certainly brought exceedingly near to equilibrium. If, therefore, a man breathes pure oxygen for only a few minutes he should be entirely protected from hemato-aero-emphysema.

Aero-emphysema in the blood. Human blood contains only about one twenty-sixth † of the total free nitrogen dissolved in the human body, and, therefore, nitrogen will flow back into the blood even if pure oxygen is breathed for a considerable length of time. Under conditions most unfavorable to health, under which blood traversing the circulation would become saturated with body nitrogen in the course of each cycle before it reached the lungs, the body would be completely denitrogenized in $26 \times \frac{20}{60} = 9$ minutes. Thus, after nine minutes no more bends could occur in the

blood. If the blood were not saturated once during each cycle, denitrogenation would take longer, but the danger of hemato-aero-emphysema would be decreased, not increased. This calculation is subject to several corrections, which would, however, not alter the result. Aviators subjected to low pressure in the "high-altitude chamber," do not get bends within a few minutes; but since bends may strike them as long as 45 minutes or more after they are in the chamber, it becomes evident that this kind of aero-emphysema cannot correctly be considered as hemato-aero-emphysema. Just where this cavitation occurs we do not know. The pain produced by it, usually in the articulations, may be very severe, but this kind of bends is usually not considered as dangerous to life. The older and well substantiated cases of fatal emphysema suffered by deep-sea divers, on the other hand, must probably still be attributed to hemato-emphysema, at least in some cases.

The fact that emphysema occurs only if a human being or test animal has been subjected to a great reduction of pressure shows that the body can stand a considerable amount of supersaturation without ill effects. Only if this supersaturation reaches the surprisingly high value of two to one will dissolved nitrogen coalesce and form bubbles. In the following pages we shall discuss not the whole problem of aero-emphysema, but mainly the conditions under which this cavitation is most likely to take place.

The fundamental reason why supersaturation of gas solutions in water occurs easily and regularly is very simple. As we have already noted, gas bubbles in the course of formation must pass through a stage where they are exceedingly small. In this pre-natal stage, as physicians call it, the gas in a bubble is not only under the hydrostatic pressure of the liquid but also under the capillary pressure of the spherical surface itself. The surface tension of water is about 73 mg/cm (milligrams per linear centimeter). The pressure, p , inside a sphere according to a well known formula ‡ is:

* Older literature assumed a longer cycle, about one minute; but the observation of radioactive salts introduced into the human blood stream has indicated the lesser value.

† The remaining nitrogen is dissolved in the extra-vascular aqueous fluids and, mainly, in the fat present in the body. For the adult man the total is not far from one liter.

‡ If a sphere contains a fluid under a pressure of p kg per sq cm, the two halves of the sphere, cut in two along any great circle, will be pushed apart by a force which is equal to the product of the pressure per sq cm and the area, in sq cm, included within the great circle. This is $\pi r^2 p$. This force is balanced by the stresses in the fabric of the sphere. It is divided among as many centimeters as the circumference measures. If we call T the stress per linear centimeter of the fabric, the total force is equal to $2 \pi r T$. Hence we have

$$2 \pi r T = \pi r^2 p, \text{ and } p = \frac{2T}{r} \text{ mg/cm}^2.$$

$$p = \frac{2T}{r} \text{ mg/cm}^2, \text{ and } r = \frac{2T \text{ mg/cm}}{p \text{ mg/cm}} = \frac{2T}{p} \text{ cm} \quad (1)$$

where T is the stress in mg/linear centimeter of the fabric and r is the radius of curvature of the sphere in centimeters.

From this formula it follows that the smaller the radius of a sphere, the greater must be the pressure inside the sphere, so long as the stress, T , in the surface remains constant. This means that inside an infinitely small bubble the pressure is infinitely great, so that the air in the bubble must pass into solution and the bubble "collapses." *

Now we can calculate from the formula given above how large a bubble must be, for any given degree of supersaturation, in order not to collapse but to grow. A bubble which is exactly between the state of collapse and the state of growth is said to be of *critical size*. The internal pressure can, obviously, not be greater than the pressure under which the gas has originally been forced into solution. The internal pressure is equal to this original pressure, if the bubble is of critical size and if no appreciable ventilation (loss of dissolved air or denitrogenation) has taken place; and p , which is the difference between internal and external pressure once dynamic and osmotic equilibrium having been established,† is equal to the difference between the atmospheric pressure to which the subject was exposed before and after ascent. If, for instance, a diver has ascended to sea level from a depth where the total hydrostatic pressure (that is, the sum of the pressures produced by the weight of the water and the weight of the air above the sea level) was five atmospheres, the difference p will be 4 kg/cm.² From this we calculate, according to equation (1), the critical radius r_1 for this specific condition.

$$r_1 = \frac{2 \times 73}{4 \times 10^6} \text{cm} = 0.365\mu \quad (2)$$

This shows that when the diver has ascended rapidly from a depth of about 40.4 meters to sea level, his blood will be supersaturated to such an extent that any nitrogen bubbles larger than 0.365 μ radius will grow, while any bubble smaller than this critical size will collapse.

Later, we shall discuss the apparent paradox contained in the fact that every bubble of 0.365 μ radius has once passed through a phase during which it was smaller than this. The importance of the notion of the *Critical Radius* will then be demonstrated more specifically.

In actual practice the blood of the diver is not saturated with pure nitrogen but with a mixture of nitrogen, oxygen, and carbon dioxide. It is assumed that since oxygen is readily eliminated by normal metabolism, it takes a small part in the bubble formation. On the other hand human blood always contains a considerable amount of carbon dioxide, part of which is loosely bound in the alkaline serum, and part merely in solution. Since the pH of the blood changes considerably (approximately from 7.3 to 7.4) ‡ in the course of one circulatory cycle, and since the carbon

* We must differentiate between dynamic equilibrium and osmotic equilibrium in a bubble. If the external hydrostatic pressure is greater than the internal hydrostatic pressure the bubble is not in the dynamic equilibrium and it will immediately grow smaller. If the internal pressure is greater, the bubble will grow larger. For osmotic pressures just the opposite is true. If the bubble is in dynamic equilibrium and if the sum of the external vapor pressures (vapor pressure of water plus vapor pressure of nitrogen plus vapor pressure of oxygen) is greater than the internal air pressure, the bubble will grow larger. If, however, the external vapor pressure is smaller than the internal pressure, air will go into solution and the bubble will collapse. Since in our deductions we always consider any bubble as being in dynamic equilibrium, we must consider collapse as due to greater internal air pressure.

† It is necessary that the internal partial air pressure, that is, the gas pressure minus the internal partial pressure of water, be equal to the vapor pressure of air in water. For the temperature covering our experiments we can neglect the vapor pressure of water.

‡ The absorption of the oxygen while the blood flows through the lungs lowers its pH and in this way raises the vapor pressure of carbon dioxide. This phenomenon of changing alkalinity actively assists the absorption of carbon dioxide from the tissues into the blood, and its expulsion from the blood when the blood passes through the lungs.

dioxide concentration itself changes also during this cycle, it is hard to say what the exact composition of the gas inside a bubble in the human blood will be at any given time.

The calculation giving us a critical radius of 0.365μ is, therefore, accurate only for experiments *in vitro*, where pure nitrogen is dissolved in pure water. Aviation medicine assumes, however, that the bubbles in the blood or in other physiological fluids are mostly nitrogen. The following discussion of the critical radius will not be affected materially by the assumption that the bubbles consist of nitrogen and that the solubility of nitrogen in blood is the same as the solubility of nitrogen in pure water. Since the solubility of nitrogen is not very different from that of air, actual numerical results of experiments made with air will correspond closely to the results which we would have obtained if we had used a gas of the exact composition of the gas mixture dissolved in the living human body.

Difference Between Deep-sea Diver's Emphysema and Aviator's Aero-emphysema

So far we have considered the emphysema of deep sea divers and the aero-emphysema of aviators to be identical. There is, however, one great difference, the understanding of which may help considerably in explaining emphysema as such, and in explaining the general phenomenon of gaseous supersaturation. We shall now consider more closely the importance of the notion of the *critical radius*. *It is incomparably more dangerous for the deep-sea diver to ascend rapidly from a depth of 40.4 meters to sea level than it is for the aviator to rise from sea level to an altitude of 11,706 meters.* Yet in both cases the decompression ratio to which the human body is subjected is the same, *i.e.*, five to one. In the first case, the pressure decreases from 5 atmospheres to 1 atmosphere; in the second case it decreases from 1 atmosphere to one-fifth of an atmosphere. As shown in Table 1, the volume of liberated gas is the same in both cases.*

In order to see whether or not the difference in effect is caused by special physiological reaction, the experiment was performed *in vitro*, pure water, saturated with air, being decompressed from five to one, and from one to one-fifth of an atmosphere respectively. The result of these experiments shows that we are confronted with a purely inorganic problem. In case 1, the cavitation was rapid and strong effervescence was observed; in case 2, the cavitation was much slower. In the first case the bulk of the dissolved air had escaped after five seconds, while in the second case, several minutes elapsed before the gas production even approximately ceased. The experiment was repeated frequently, and though the time differences were not always so great, they were in all cases quite striking. This is a rather surprising result, since, as stated above, the volumes of gas produced are exactly the same in both cases and what we observe *in vitro* is volume, not weight. What injures the diver also is volume, not weight.

Since the experiment *in vitro* gives the same result as the well known observation *in vivo*, we shall restrict ourselves to seeking an explanation of the former.

Table 1 shows that in case 1, five times more nitrogen (measured by weight) escapes than in case 2, but that, since the density of the escaped gas is five times greater in case 1 than in case 2, the volume is the same in each case, *i.e.*, 80 cc per liter. One thing, however, is different in the two cases—the critical radius.

Table 2 shows that, as was found from equation (2), the critical radius r_1 of case 1 is only 0.36μ . In case 2 the pressure p is 0.8 kg/cm^2 and the critical radius r_2 is

$$r_2 = \frac{2 \times 73}{0.8 \times 10^6} \text{cm} = 1.8\mu \quad (3)$$

* To be quite accurate one should add (to the hydrostatic pressure of the water surrounding the diver) the normal pressure produced by the body tissues. Since this is constant it would explain part of the phenomenon by somewhat cutting down the ratio of decompression. As the experiments *in vitro* show, this cannot explain the whole phenomenon.

Table 1. Air Dissolved in, and Escaping from, One Liter of Water

| Pressure (atm) | Air dissolved | | Air escaping | |
|--|---------------|-------------|--------------|-------------|
| | Weight* (mg) | Volume (cc) | Weight *(mg) | Volume (cc) |
| Case 2 $\left\{ \begin{array}{l} 0.2 \\ \uparrow \\ 1.0 \end{array} \right.$ | 4 | 20 | 16 | 80 |
| | 20 | 20 | | |
| Case 1 $\left\{ \begin{array}{l} 1.0 \\ \uparrow \\ 5.0 \end{array} \right.$ | 20 | 20 | 80 | 80 |
| | 100 | 20 | | |

* The air volumes given are correct for a temperature of 17° C. The same table is correct for nitrogen at a temperature of 7° C. The weights are given in round numbers.

Table 2. Critical Dimensions of Air Bubbles

Case 1. Water is saturated under a pressure of 5 atm abs. and the pressure is released to 1 atm abs.
Case 2. Water is saturated under a pressure of 1 atm abs. and the pressure is released to 0.2 atm abs.

| | Critical radius | Critical volume | Number of molecules | Water volume from which air is taken |
|--------|-----------------|-----------------|---------------------|--------------------------------------|
| Case 1 | 0.36 μ | 0.20 μ^3 | 28 $\times 10^6$ | 12.8 μ^3 |
| Case 2 | 1.8 μ | 26 μ^3 | 690 $\times 10^6$ | 1620 μ^3 |

Columns 3 and 4 of Table 2 will be discussed later. The mathematical meaning of the critical radius as derived in Table 2 is very simple. It means: (1) if the water is saturated at five atmospheres' absolute pressure and the pressure released to one atmosphere absolute, no gas bubble can be formed unless its radius is first equal to, or greater than 0.36 μ , and (2) if water is saturated at one atmosphere absolute pressure and the pressure then released to one-fifth of an atmosphere, no bubble can be formed unless its radius is first equal to or greater than 1.82 μ . This is obviously absurd, since as a matter of fact, we see bubbles coming up where there were no bubbles before, and no bubble can possibly be formed unless it is first a very small bubble.* It would be like the case of an animal the embryos of which are never capable of living unless they are first, say a quarter of an inch long.

Since the result of the calculation given above does not agree with the observed facts, it is certain that at least one of the assumptions made was incorrect. As far as we can see, the assumption which does not strictly correspond to the facts is that

* Vibrations, sound waves and ultrasonic waves, and especially nodes, because of the temporary reduction of pressure which they engender, can diminish locally and temporarily the number of molecules needed to produce cavitation. In this case two possibilities exist: either the embryonic bubble has time, during the short period of favorable conditions, to grow into a bubble of more than critical size, or it has not the time needed for this growth. The bubbles may then be large enough and numerous enough to produce visible opalescence. This opalescence will then disappear at the end of each low-pressure period. To the human eye such an intermittent cloudiness would seem to be steady, and the clear phase of the phenomenon could be seen only by means of a stroboscope. The effect of acoustic and ultrasonic waves has been discussed by several authors. (See: Reynolds, O., "Papers on Mechanical and Physical Subjects," vol. 2, p. 578, New York, The Macmillan Company, 1901, Bondy, C., and Söllner, K. "Mechanism of emulsification by ultrasonic waves," *Trans. Faraday Soc.*, 31, 835-843 (1935); Boyle, R. W., "Ultrasonics," *Science Progress*, 23, 75-105 (1928); Kundt, A., and Lehmann, O., "Ueber longitudinale Schwingungen und Klangfiguren in cylindrischen Flüssigkeitsäulen," *Ann. Phys. Chem.*, 153, 1-12 (1874). The latter have especially observed the formation and disappearance of bubbles in non-saturated liquids. It is quite possible, as has been pointed out by Maurice B. Visscher (private communications), that under complete absence of vibrations cavitation as observed in super-saturated solutions would not occur. See also paper by A. Einstein in Vol. I of this series.

air bubbles grow continuously and not discontinuously, *i.e.*, that air is a homogeneous fluid, whereas we know that it is composed of individual molecules. We shall now show that this incorrect assumption must be held responsible for the disagreement between calculation and observed facts.

If a single molecule were large enough to produce a nucleus or seed, it is obvious that a bubble could be started by any one molecule of nitrogen or oxygen. But it takes millions of molecules to produce a bubble equal to or greater than the critical size. Let us, therefore, calculate exactly how many molecules are contained in a bubble of critical radius in case 1 and in case 2. From the radii given we calculate the volume as $V_1 = 0.205\mu^3$ and $V_2 = 25.7\mu^3$. It is known that under standard conditions (760 mm of mercury and 0°C) a volume of 22.4 liters of any gas contains 6.02×10^{23} molecules. In case 1, the inside pressure is 5 atmospheres absolute, and in case 2 it is 1 atmosphere. The respective numbers of molecules in case 1 and in case 2 are, therefore

$$n_1 = \frac{6.02 \times 10^{23} \times 5 \times 0.205}{22.4 \times 10^{15}} = 27.6 \times 10^6$$

and

$$n_2 = \frac{6.02 \times 10^{23} \times 1 \times 25.7}{22.4 \times 10^{15}} = 690 \times 10^6$$

This proves that no single molecule of nitrogen or oxygen could possibly be considered as a seed for the birth of a bubble. How then is it possible for any bubble to pass through its embryonic stage before reaching critical dimensions and starting to grow normally? Now this question can be answered only by the theory of probabilities. It may seem exceedingly improbable that at any given point of the super-saturated solution 27.6 or 690 million molecules could meet and start a bubble growing; but the field is very large. A liter of water does not contain millions but billions times billions of air molecules.* What is exceedingly unlikely to happen at any one point of the field will probably occur somewhere in the whole field, not only once but many times.† Whenever molecules of nitrogen or oxygen, or both, happen to meet at one point of the solution and whenever their number is smaller than 27.6 or 690 million respectively, nothing happens; or, to express the same idea in other words, a bubble is formed which dies *in statu nascendi*. (See column 3 of Table 2.)

This forms the great majority of cases; but it occasionally happens that at one place or another more than 27.6 or 690 million molecules do meet, or at least come close enough to break the film of water separating them. Just how thin this separating film must be in order to break, we do not know. Then, and only then, nuclei or seeds are produced of sufficient vitality to grow and after they have grown, to make the whole solution appear milky. Bubbles of the critical size are in the colloidal zone, which may be reached by the aggregation of sub-colloidal particles, as well as by the dispersion of super-colloidal particles. In the case of gas dispersions in water, the latter phenomenon cannot take place because a bubble, once it is small enough to go into solution, will always disappear entirely, since the smaller it is the greater will be the interior pressure.

* A simple calculation shows that a liter of water, saturated at 1 atmosphere and therefore holding about 20 cc of dissolved air (standard conditions) contains 5.4×10^{20} air molecules and, if saturated at a pressure of 5 atmospheres, contains 27×10^{20} air molecules.

† In physics as well as in medicine or in any other science many instances are known where it is probable that a certain "accident," very unlikely to happen in any one case, will, in a larger field, occur with a probability which is so great that it is a certainty. Any particle of iron hydroxide, for instance, resting on the bottom of a container filled with water, will probably get as many molecular blows from one side as from the opposite side, and yet if we observe long enough and under proper conditions we are sure to see it making a sudden side motion as a result of having received during a certain fraction of a second many more blows from one side than from the other. This is the basis of Brownian motion.

The turbidity of gases and liquids in the vicinity of the critical state is due to the formation of colloidal particles of condensing liquid in the gaseous phase because of pressure and/or cooling. A. Einstein demonstrated this mathematically in his paper in Vol. I. of this series.

Now we are able to give an answer to the question posed above: Why do we get more bubbles in case 1 than in case 2? The obvious answer is that it is much more probable that 27.6 million air molecules will meet at one place in the water solution than that 690 million will meet, especially if the volume from which the 690 million have to assemble is less densely populated. A simple calculation shows, indeed, that in case 1 the necessary air must diffuse from a volume of 12.8 cubic microns, whereas in the second case the required number of molecules must come from a volume which is 5³ times larger, that is, 1606 cubic microns. The larger the volume from which the scattered molecules must congregate, the less the probability that a congregation of sufficient size will be formed.

Table 2 demonstrates the difference between case 1 and case 2 (see especially column 4). This is strikingly illustrated by Fig. 1, which we owe to the courtesy of Dr. W. Boothby.

FIGURE 1. Relative size of the air bubbles and the water volume from which the molecules must come.

As far as we know today the theory of probabilities enables us to understand why it is more dangerous for a deep-sea diver to come up from a depth of 40.4 meters than it is for an aviator to go up to an altitude of 11,706 meters. In both cases the volume of nitrogen eventually escaping from tissues and blood is the same, but in the second case the cavitation is slower and for this reason a larger proportion of the nitrogen escapes through the lungs and the probability of harmful cavitation is very much less.

Methods for the Prevention of Emphysema

We may add here a résumé of the methods used to prevent bends in deep-sea diving and in aviation. Since bends are produced by nitrogen bubbles, it follows directly that if we exclude nitrogen we prevent bends altogether.

In deep-sea diving an obvious solution would be the administration of pure oxygen to the diver from the moment he begins his descent into the sea. This solution, though simple to the physicist, is prohibited by the physician. If a guinea-pig or a goat is kept for any length of time in an atmosphere of pure oxygen the epithelium of its lungs is affected by this five-fold excess of oxygen somewhat as it is affected by chlorine. It causes damage to the enzyme systems and the usual obvious result is severe lung injury which may lead to death. If such results follow when the partial pressure of oxygen is raised in the ratio of 21 to 100, how much more marked would they be with a ratio of 21 to 500, which would, for example, develop if the diver had to reach a depth of 50 meters!

For many years, therefore, deep-sea divers were given ordinary compressed air. Depths greater than 50 meters were considered somewhat dangerous and no useful work was ever done at greater depths than 90 meters.* (U. S. Navy, Honolulu, 1915)

Three elementary precautions against bends are prescribed for deep-sea diving: (1) The diver must under no conditions go deeper than 100 meters, preferably not deeper than 80 meters. (2) He must not stay too long at great depths—not more than ten minutes beyond 64 meters. (3) From any depth beyond ten meters he must come up slowly; and the longer he has remained down, the slower he must ascend.

J. S. Haldane was the first to work out a convenient table indicating at what levels intermediary stops must be taken during the ascent of the deep sea diver. The number of these stops and their length depend obviously upon the time the diver had remained at his greatest depth. With permission of the Yale University Press, we reproduce here part of this table as given in "Respiration," by J. S. Haldane and J. G. Priestley. (See p. 1092.)

From a purely biological point of view it would certainly be more efficient not to prescribe complete stops and rapid ascents between these stops, but to prescribe for every level reached during ascent, the permissible speed of ascent as a function of the maximum depth reached, and of the time spent there. From a master diver's point of view, however, it would be far more difficult to establish specific and continuously changing speeds than to arrange for a certain number of complete stops of prescribed lengths and at prescribed levels.

The safety of deep-sea divers has furthermore been greatly increased by the invention of the decompression chamber, also described by J. S. Haldane. If for any reason a diver had been raised too rapidly or if he shows any signs of bends, he is immediately introduced into this chamber. There the pressure is raised to about one-half of the greatest pressure to which the diver had been submitted, and after he has remained for some time at this pressure, it is gradually reduced, according to Haldane's tables, or more slowly if any new signs of bends appear. This is far more comfortable than the older method of re-submerging a diver if he suffers from bends, and it is also much safer.

The isolation of large amounts of helium during World War I has, however, permitted another solution of the problem—inhalation of a mixture of oxygen and helium. Helium is less soluble in water than nitrogen, and what is even more important, due to its lower molecular weight it diffuses out of the body more rapidly than nitrogen. Another important advantage of helium over nitrogen is that the former does not possess the anesthetic properties which the latter shows at high pressures. For these reasons the mixture of oxygen and helium has allowed modern divers to break the older depth records of about 100 meters without danger.

A similar solution had been suggested for aviation when a very fortunate physiological discovery was made: Man, in contradistinction to the guinea pig and the

* This does not, of course, apply to rigid diving suits or bathyspheres in which the diver is not subjected to the exterior water pressure.

Table 3. Stoppages During the Ascent of a Diver after Ordinary Limits of Time from Surface

| Depth (feet) | Time from surface to beginning of ascent | Approximate time to first stop (min) | Stoppage in minutes at different depths ¹ | | | | | | Total time for ascent (mins) |
|-----------------|---|--|--|-------|-------|-------|-------|-------|---------------------------------|
| | | | 60 ft | 50 ft | 40 ft | 30 ft | 20 ft | 10 ft | |
| 0-36 | No limit | 1 | — | — | — | — | — | — | 0-1 |

During each stoppage the diver should continue to move his arms and legs. Haldane gives also a table, not reproduced here, to be used in case the diver had been subjected (accidentally) to a longer time of submersion.

goat, can tolerate pure oxygen at partial pressures up to one atmosphere for long periods of time. Instead of breathing ordinary air until the altitude is reached (about 10,000 to 12,000 feet) at which oxygen is needed, the aviator should breathe pure oxygen from the very start, or, better yet, for some time before the start of any flight which is likely to reach an altitude of 34,000 feet or more. If the pilot intends to reach the lower part of the stratosphere, say 36,000 feet, if the ascent is to be made with a fast-rising plane and if the pilot intends to stay in the stratosphere more than a very short time, it becomes imperative that pure oxygen be breathed a considerable time before the actual start of the flight.

Greater altitudes than 40,000 feet must not be sought without pressure suit or pressure cabins because, although bends could be avoided, the partial pressure of oxygen, even if pure, is insufficient to sustain life beyond this altitude.*

We have discussed the fact that it is much less harmful for an aviator to ascend rapidly to an altitude where the barometric pressure is one-fifth of normal than it is for the diver to ascend to an absolute pressure of one-fifth of the pressure to which he was subjected. This now well known observation was anticipated to a certain degree by results from experiments conducted by the British Admiralty Committee as described by J. S. Haldane. Haldane states that it is permissible for deep-sea divers to decompress rapidly from relatively low pressures in the ratio of 2.25 to 1. For somewhat higher pressures, the safe ratio of rapid decompression is 2 to 1 and for pressures above six atmospheres it is only 1.75 to 1. The fact that it is safe for the aviator to decompress rapidly in the ratio to 4 to 1 (ascending from sea level to 33,000 feet) is nothing more than an extrapolation of the phenomenon described by Haldane.

This suggests that, since it is safe for the aviator to ascend rapidly from sea level to 33,000 feet, it would be equally safe to ascend rapidly from 6000 feet to about 39,000 which (for lack of oxygen) is about the upper level to which any aviator should ascend without a pressure suit. This indicates a great superiority of lighter-than-air aircraft as carriers of airplanes. If such a carrier, which is always of the Zeppelin type, cruises at a level of 6000 feet, its passengers are ready at any moment to ascend to the greatest heights without any previous denitrogenation and without danger from aero-emphysema.

* Although the total pressure of pure oxygen (141 mm at 40,000 feet) would be sufficient to sustain normal life, too large a part of this oxygen is replaced inside the lungs by water vapor (the partial pressure of which is 47 mm at blood temperature) and by carbon dioxide (the partial pressure of which is also about 47 mm). At 40,000 feet the remaining partial pressure of oxygen in the lungs even if pure oxygen is given, is, therefore, only $141 \text{ minus } 94 = 47 \text{ mm}$.

The Action of War Gases

CHAUNCEY D. LEAKE and DAVID F. MARSH

Medical Schools of the University of Texas and the University of Georgia

Before taking up the mechanism of the action of war gases, it may be well to consider the psychological and political aspects of this military weapon, which, apart from its biological effects, imposes the threat of panic among civilians conditioned by fear. Once the popular ignorance relative to "gas" is replaced by knowledge as to how relatively weak a weapon it is against civilians and how effective are simple protective measures against it, the more serious danger of panic based on ignorance will be overcome.

Since high explosives are vastly more effective against cities than is an equal tonnage of gas, the limited carrying capacity of airplanes will preferentially be devoted to demolition and incendiary bombs, whose effects do not evaporate or dissipate. Furthermore, while fatal military casualties due to gas in the last world war amounted to only about 2 per cent, with all other weapons the average was about 28 per cent; and with gas civilians are in a much safer position than the military. Soldiers have to seize, occupy and hold territory in defiance of chemical attack, whereas civilians may take shelter or may move to unexposed positions. Thus, apart from exceptional situations, civilians do not need the elaborate protection necessary for soldiers.

However, the mere threat to use gas, made by the Germans, was sufficient to make the British at the outbreak of the present war divert to the manufacture of gas masks and the like considerable amounts of steel and rubber, which might otherwise have been utilized in making offensive weapons. Gas has not yet been used by the military in the present war of movement, though it probably will be used in static battles or in desperate situations.*

It is very important to give civilians as much information about war gases as possible—as to how they act biologically, and how their effects may be prevented or reduced. If this is carefully done it will become readily apparent that one may reasonably take care of oneself no matter what kind of war gas may be suspected.

It is extremely important to point out that all explosions release "war gases." In addition to carbon monoxide, which is odorless, colorless, and non-irritating, but which fortunately dissipates very rapidly, there are also "nitrous fumes" and the effects of "blast." The action of any of these accompaniments of explosions may be confused with the action of war gas. "Nitrous fumes" are brownish, heavy vapors which will irritate the eyes and nose and lungs, and cause effects very similar to the war gases. The methods of protection devised for war gases are equally effective against "nitrous fumes," or even against hot oil smoke or the smoke and fumes from other incendiaries. Reasonable appreciation of the biological action of war gases will tend to remove the untoward psychological effects of fear of exposure to them.

Biological Action of War Gases

The intensity of biological action of a chemical agent (I) is dependent upon (1) *dosage* (D), in terms of mass of chemical per mass of living material; (2) *ratio* of the *rate of absorption* (rA) and distribution of the drug through the living tissue to its *rate of excretion* (rE) or destruction; (3) *physico-chemical properties* (Ch) of

* See paper on Chemical Warfare in Vol. III of this series, by J. Alexander.

the drug, such as its differential solubility in different solvents, its polarity, its molecular configuration and energy organization, its dissociation characteristics and its optical properties, and (4) *peculiarities (P) of the particular type of living tissue involved*, such as its age, its metabolic and allergic states and its enzyme balance. These factors may be succinctly summarized in the following non-mathematical formula:

$$I = \left[D \frac{rA}{rE} \right], Ch, P.$$

The concentration (C) of the chemical in the tissues at any given moment after administration is given by the product of D and the ratio of rA to rE .

Appreciation of these factors may help to understand the difference in action of various war gases and the variation in intensity of effect of the same war gas in the same concentration on different individuals. A suitable analogy to the latter situation is the difference in response of different people to the same intensity of sunlight or poison ivy.

For our present purposes we may consider as ordinary war gases the lung irritants, like phosgene or chloropicrin, and the vesicants, like mustard gas and lewisite. We may thus disregard such unusual possibilities as catalyzed cyanides or metallic carbonyls, and such gaseous associates of demolition bombs and incendiaries as carbon monoxide, "nitrous fumes," "blast," hot-oil smoke or phosphorus. However, the tissue aggressiveness of "nitrous fumes" suggests that these deserve attention in the same way as ordinary war gases.¹

As shown in Table 1, the ordinary war gases may be indicated to be chemical relatives of such types of aliphatic hypnotic and inhalation anaesthetic agents as alcohol, chloroform and ether. People generally recognize the locally irritating powers of these common compounds. Their gas relatives may owe an increased irritative action to aggressive factors associated with altered halogenation and polarity.

Table 1. Chemical Relations Between Common Irritant Drugs and War Gases

| Aliphatic irritant | Corresponding war gas |
|----------------------------|---|
| Alcohol $H-CH_2CH_2-OH$ | Ethyl dichloroarsine $H-CH_2CH_2-AsCl_2$ |
| Chloroform Cl_3C-H | Chloropicrin Cl_3C-NO_2 |
| Ether $(H-CH_2CH)_2O$ | Mustard gas $(Cl-CH_2CH_2)_2S$ |

These war gases usually contain a rather labile halogen, like chlorine or bromine, which, with the hydrocarbon portion, may be considered to be relatively more attracted to fat and protein than the rest of the molecule. On the other hand, the war gases also contain more potent polarizing elements or radicals, like oxygen, sulfur, arsenic, a nitro group or oxime, which may be relatively more attracted to water or which may reduce the strength of the halogen bond. Differences in relative water-fat solubilities and in ease of hydrolysis may be important factors in the site of action or in the onset or duration of action, as exemplified in the contrast between lacrimators and vesicants.

A common theory explains the action of war gases on the basis of splitting off

¹ Proceedings of a Board of the Chemical Warfare Service appointed for the purpose of investigating conditions incident to the disaster at the Cleveland Hospital Clinic, Cleveland, Ohio, on May 15, 1929. Edgewood Arsenal, Maryland, Lieutenant-Colonel Walter C. Baker, C. W. S., commanding. U. S. Government Printing Office, Washington, 1929, 104 pp.

halogen, with immediate irritant effect from the resulting halo-acid. This may occur promptly on the wet surfaces of eyes, and of mucous membranes of the nose, mouth, throat and lungs, with such agents as the lacrimators, phosgene, and lewisite. On the other hand, as with mustard gas, the partition coefficient may favor absorption into the cells, after which the halogen may split off. The resulting halo-acid within the cell may alter enzyme systems, permeability of the surface membrane or protein equilibria, in such a way as to kill the cell. While such formation of acid may occur, it would have to exceed the buffering capacity of cells and tissues, and this might require relatively large amounts in order to pass the threshold. Neutralization by cellular buffers would be expected to produce the corresponding halide ion which would not markedly affect cellular function. At any rate, exhaustion of the buffer mechanism should reduce further hydrolysis. Direct experiment has shown that molecularly intact mustard gas may be isolated from deep skin layers many hours after absorption. Again, acid injury usually involves protein denaturation and precipitation, whereas war gas injury is characterized more by disturbances of cellular permeability, with swelling, protein hydrolysis and cellular disintegration.² Another theory of mechanism of action may be considered. This relates to the relatively rigid molecular configuration of the war gas molecule as compared to the cell membrane. The latter is interpreted as a water-lipoprotein interface.³ Portions of the war gas molecule seem to be relatively lipo-proteophilic, while other portions seem to be more hydrophilic. If enough war gas molecules are present at the cell surface, distortion of the interface may occur. This would result from orientation of the war gas molecule in accordance with the selective affinity of different parts of the molecule for water and lipoprotein, respectively. If this affinity and the interatomic angle forces in the war gas molecules are greater than the surface-tension forces which maintain the normal cell surface, torsion may follow, with changes in permeability of the surface film, with resulting swelling and further distortion and strain of the surface membrane. This may comprise the initial inflammatory response to war gases, which may go on to cellular rupture, vascular breakdown, autolysis and necrosis, as so well described by Livingston and Walker.² Tight packing of cells, as may be accomplished by high ascorbic acid intake,⁴ would tend to reduce the intensity of this reaction, as Livingston and Walker noted.² Another factor of importance may be combinations of parts of war gas molecules with tissue proteins or amino-acids, with resulting allergic reactions to such combinations, and followed by cellular necrosis.

Whichever mechanism occurs, the prolonged tissue response to war gases would subsequently include the slow removal of necrotic debris, to be followed by gradual repair. In the case of lung irritants, this sluggish process indicates the need for protracted oxygen administration as well as for prophylaxis against psychiatric pneumophobia.

In the biological effects of war gases, therefore, it seems that one or more of the following factors is concerned: (1) relative water, fat and protein solubility, both in transport and in relation to cell surface; (2) relative ease of hydrolysis, with relation to possible formation of halogen acid and the effects of the rest of the molecule; (3) distortion of cellular surfaces due to the molecular configuration of war gas molecules or to their secondary valence forces, and (4) effects of war gas molecules on pH, redox potential and colloid, interface and enzyme equilibria.

As in the case of sunburn or exposure to poison ivy, once the process of war gas injury is under way, one may hope for benefit only on the basis of symptomatic relief, of aiding the removal of necrotic tissue and of promoting repair. It would seem wise,

therefore, to train civilians in "self-aid" against war gases in suspected contact with war gas, since first-aid or professional care is apt to be too late.

In order to reduce confusion of thought to a minimum and thus to help prevent panic in suspected attack with war gas, "self-aid" should be devised in as simple a manner as possible. Recommendations should be based on the least common denominator of effectiveness for whatever is likely to be used by a smart enemy. Since mixtures of war gases are certain to be employed, it seems unwise to worry about specific identification and specific management of potential injury, if such identification is based on such an indefinite procedure as smell.

Absorption of the ordinary war gases and their many obvious chemical relatives may be inhibited by neutralizing hydrolysis, oxidation or adsorption. For civilian use, these methods may be improvised from materials readily available in homes. Since the war gases in general are decomposed or poorly soluble in water, a wet cloth tied over the nose and mouth is a relatively effective barrier to the passage of such vapors, including oil smoke and "nitrous fumes," to the nose, throat and lungs.

The most readily available effective oxidants are the common kitchen bleach solutions, such as "Clorox." These are buffered 3 to 5 per cent sodium hypochlorite solutions and are non-irritating for blotting on the skin, but should be diluted for application to mucous membranes, for washing the skin or for wetting cloths to breathe through. As is well known, such a solution reacts promptly with mustard gas, 2,2'-dichlorodiethyl sulfide (B.P. 217°), converting it to the non-toxic crystalline 2,2'-dichlorodiethyl sulfoxide (M.P. 110°) and probably to other non-toxic sulfones. The use of such sodium hypochlorite solutions for the prevention of mustard gas injury has been widely advertised in England.⁵ Confirmation of their effectiveness against both mustard gas and lewisite has been obtained by Professor T. D. Stewart, of the University of California, on scores of human subjects, and by ourselves on humans and experimental animals. It is immaterial whether oxidation of mustard gas produces the sulfoxide or sulfone, or further decomposition, or what is produced on treating lewisite with hypochlorite. Direct experiment shows that such treatment of these compounds or their obvious chemical relatives results in non-toxic residues.

For alkaline hydrolysis, sodium bicarbonate solutions around 2 per cent may be readily prepared in a black-out room by dissolving a teaspoonful of baking soda in a glass of water. Such a solution is helpful in washing out the eyes, nose and throat in suspected war gas irritation, or for wetting cloths to breathe through.

The most suitable and readily available detergent adsorbent is lather from ordinary soap and water or soap flakes or tincture of green soap. This is particularly useful, as are hypochlorite solutions, in preventing skin injury from suspected contact with blister gases. The data in Table 2 show the value of soap and hypochlorite in reducing skin injury (in a rather sensitive test subject) from mustard gas application, in comparison with such a mustard gas solvent as kerosene.

The common blister gases are soluble in kerosene, gasoline, acetone, carbon tetrachloride and similar fat solvents. During World War I, it was naturally assumed that such solvents would be useful in removing liquid blister gas splashes from the skin. We have found no data to support this idea. However, current advice to civilians retains this recommendation. It is to be remembered that kerosene, gasoline and acetone may be absorbed through the skin, and that, like carbon tetrachloride, they are themselves skin irritants. They are also solvents of low viscosity and tend to spread easily. It is unlikely that they would be used carefully under the conditions of excitement existing in the crisis of suspected war gas contact. Our experiments show (Table 2) that even under controlled conditions they are much less satisfactory than lather or hypochlorite.⁶

Pharmacologists have the obligation of establishing and explaining the facts regarding the action of chemicals on living things. They have the privilege of applying such information to whatever practical problem may be appropriate. With respect to war gases, present pharmacological information suggests that the simplest and most effective advice for civilian protection against such gases might be: (1) obey air-raid rules, taking refuge during an alarm in an air-raid shelter or black-out room, with doors and windows shut and the windows screened or heavily curtained on the inside to prevent injury from flying glass, if bombing occurs; (2) if the shelter is broken open by bombing, and if war gases are suspected by fogs, peculiar odors, smarting or stinging in the eyes, nose or throat, or by coughing, sneezing or gasping, or by any other symptoms, tie a cloth soaked in baking-soda solution, or diluted

Table 2. Average Character of Skin Response in Rabbits to 0.05 CC 10 Per Cent Mustard Gas (HS) in Ether, with Treatment Consisting of Thrice Blotting Area of Application (Rough Circle 10 mm in Diameter) One Minute After Applying HS with Gauze Soaked in Kerosene, Soap and Water, or 3 Per Cent NaOCl (Clorox), Respectively *

| Day | Untreated | Kerosene | Soap | 3% NaOCl |
|-----|---|---|--------------------------------|--------------------------------|
| 1 | Intense erythema and edema | Moderate erythema, slight edema | Diffuse erythema, edema | Diffuse erythema |
| 2 | Diffuse erythema and edema, central blanched area | Diffuse erythema and edema, central blanched area | Blanched area, 10 × 15 mm | Blanched area, 10 × 15 mm |
| 5 | Deep hemorrhagic necrotic area, 10 × 12 mm | Hemorrhagic necrotic area, 12 × 15 mm, with diffuse necrosis at edges | Thin scaly necrosis, 8 × 10 mm | Thin scaly necrosis, 8 × 10 mm |
| 15 | Heavy adherent scab, 10 × 12 mm | Broad adherent scab, 15 × 20 mm | Thin flakey scab, 8 × 10 mm | Thin flakey scab, 8 × 10 mm |
| 22 | Heavy adherent scab, 10 × 12 mm | Broad adherent scab, 15 × 20 mm | Light scar | Light scar |

* No significant difference from untreated areas observed after application (as above) of either 3 per cent H_2O_2 , acetone or "bleach paste." Treatment with 5 per cent NaOH in 30 per cent glycerine seems to increase inflammatory reaction during the first week, producing a deeper and slower healing necrotic area. Ten per cent benzoyl peroxide in nona-ethylene glycol seems to have little effect on HS reaction during first day or so, but seems to reduce necrotic reaction and time required for healing. However, 10 per cent benzoyl peroxide in talc affords no protection when dusted on skin previous to exposure. Observations similar to the above have been obtained with lewisite; healing, however, is more rapid.

kitchen bleach solution, over the nose and mouth to breathe through, keep it wet, shut one eye and squint through the other, lie down with head in arms; (3) if eyes, nose or throat are irritated, wash them with a solution of a teaspoonful of baking soda in a glass of water; (4) if splashes of liquid are suspected on the skin or clothes, throw the outer clothing out the window, blot the skin, splash promptly and repeatedly with a cloth wet with kitchen bleach solution, lather thoroughly and frequently with soap and rinse copiously with water. If subsequent injury results, the management is symptomatic at a casualty station or hospital.

These considerations were fully reviewed early in 1942 by the San Francisco and Alameda Committees on the Medical Aspects of War Gases. Special discussions along these lines have been widely published on the West Coast for civilian informa-

tion.⁷ Experience has shown that these suggestions for "self-aid" in handling suspected war gas exposure are appreciatively received by the public because they are simple and sensible. Recently these suggestions in substance have been included in "official" recommendations.⁸

Summary

War gases act on people economically, politically and psychologically, as well as in direct biological ways. It is wise to offer all available information on war gases to the public in order to dispel ignorance, reduce fear, and prevent panic from their possible use against civilians.

Infective Aerosols

PROF. M. W. JENNISON

Department of Biology and Biological Engineering, Massachusetts
Institute of Technology, Cambridge, Mass.

Introduction

Broad consideration of the aerial dissemination of disease involves, first of all, setting up certain categories of the disease-producing agents, of the mode of their transmission in air, and of the organisms or substances which they may infect. In this review we are concerned particularly with those *air-borne, living* entities which, as a result of their *growth* in the *living* body, are potentially able to produce an *infection* or disease. These atmospheric colloids we shall term *infective aerosols*. Various bacteria, viruses, and molds (as spores) are the types of microbes most commonly involved as infective aerosols. The transmission of disease agents by insects will not be considered as belonging in this category. Also excluded by this definition, though they will be touched upon briefly, are "diseases" of inanimate objects, and pollen allergies. (Pollens, although they may be air-borne and may produce reactions in the animal body are not, strictly speaking, *infective* agents.) Although many plant diseases are air-borne, primary attention will be given to infective aerosols in relation to human diseases. Fundamental points as regards aerial infection are the viability of the organisms in the air, that is, how long they will remain alive and *infective*, and their dilution in the air.

The infective agents may be borne *by* the air, or the air may merely be the medium *through* which infection is carried—for example, by insects. In the former case (strictly air-borne infection), both air movement and particle size are factors which determine whether or not the infective agents will remain suspended in the air, that is, whether they are *aerosols*. Aggregates of the single units or cells of infective agents may occur, so that in the air the average size of infective aerosols probably is greater than that of the single components. A typical bacterial cell is about 1-2 μ in size; virus particles are all less than 1 μ , and some are as small as 0.01 μ . The size range of various kinds of mold spores is from 3 μ to 50 μ or more. Most wind-borne pollens are between 20 μ and 60 μ .

Both living plants and living animals are susceptible to various diseases that may be air-borne. Infection of non-living organic substances by microbes also may

⁷ Articles on war gases by J. F. Hildebrand (*The Commonwealth*, 1942; *San Francisco Chronicle*, Feb. 15, 1942), M. Silverman, (*San Francisco Chronicle*, March 15, 22, 29, Apr. 5, 1942) and W. F. Mould, leading West Coast newspapers through June and July, 1942

⁸ *J. Am. Med. Assn.*, 119, 889 (July 11, 1942).

take place, resulting in spoilage, as, for example, in the "diseases" of beer, and in the mildewing of textiles. The principal types of air-borne microorganisms causing diseases of animals are bacteria and viruses; of plants, mold spores and to a lesser extent bacteria. Non-living organic substances may become infected by molds, bacteria, or yeasts.

It may be well here to stress the point that the demonstrable presence, in the air, of living pathogenic microbes cannot in itself be taken as proof that infection is necessarily caused thereby, but only makes evident the possibility of such infection. As will be brought out later, there is abundant evidence for the presence of potentially infective aerosols of both plant and human origin. However, since some degree of contact between persons is hard to rule out, and for other reasons, it is difficult to obtain sound experimental proof of the *relative* importance of the transmission of *human* diseases by strictly air-borne means compared to other methods of spread.

Historical Perspective

The idea that disease might be transmitted from person to person through the air dates back to antiquity. Some of the outstanding historical developments in connection with the modern concepts of air-borne human infection have been discussed by Chope and Smillie,⁴⁴ and some of the following historical background is summarized from their paper.

Four hundred years before Christ, Hippocrates stated that it appeared that the cause of disease should be found in the air, particularly when it was tainted by *morbid miasmas*. The concept of "miasmas" flourished during the middle ages. The germ theory of disease was anticipated by more than 300 years by Fracastorius when he suggested (1546) that contagious diseases were caused by "seeds of contagion" which probably were carried in the air. The disease malaria ("bad air"), the germs of which are now known to be carried by certain kinds of mosquitoes, was long thought to be caused by atmospheric miasmas, although its connection with the mosquito was hinted at over 400 years ago.²

The germ theory of fermentation and of disease, and the first scientific demonstration of air-borne infection (1861), were due to Pasteur.¹⁵⁸ As a consequence of these discoveries many persons concluded that all or nearly all diseases were spread through the medium of the air. However, the rise of bacteriology during the subsequent forty or fifty years did much to break down this hypothesis, particularly as regards the intestinal diseases. Many diseases were shown to be transmitted by other routes, *e.g.*, by contaminated water and food, by contact, and by insects, and the number of diseases thought to be air-borne decreased correspondingly. This decrease was the more real since investigators were unable to demonstrate recognized pathogenic organisms in the air, even in those diseases which are spread through discharges from the respiratory tract. Flügge⁸² in 1899 was unable to obtain any appreciable numbers of organisms on culture plates exposed farther than a few feet from persons coughing and sneezing, and concluded that the expelled droplets settled out of the air quickly. Thus *droplet* infection (which resembles contact infection more than it does strictly air-borne infection) was shown to be possible within a short radius, but at the same time strictly air-borne microbes were not demonstrated, and therefore air-borne contagion seemed eliminated, even in respiratory infections. The negative evidence obtained by the experiments of Flügge and contemporary investigators (see²⁵²) carried great weight, but as has been remarked²³⁸ the case against air-borne infection was dismissed with a Scotch verdict of "not proven." In 1912 Chapin³⁷ reviewed the literature on the transmission of contagious diseases. He concluded that close personal contact was the most important factor in the spread of respiratory diseases, and that there was no good clinical evidence that the common diseases are airborne.³⁸ These conclusions regarding contact (including droplet)

infection were accepted generally, the theory of air-borne infection discredited, and for the next two decades little attention was paid to the latter mode of disease transmission.

The whole question was reopened following an epidemic of psittacosis (parrot fever) in the National Institute of Health at Washington in 1930.¹⁵⁰ Epidemiological studies indicated that the infection in this instance was air-borne. Consequently a new stimulus was given to investigations of the role of air in the transmission of infection. Development of more sensitive bacteriological air-sampling techniques⁴⁹ has led to abundant proof of the presence of pathogenic aerosols. Recent bacteriological and epidemiological evidence indicates that respiratory disease of air-borne origin is, in certain situations at least, an actuality, and that this method of spread is more important than has hitherto been supposed.^{1a, 25, 240} There is no question but that close personal contact is a very important factor in the transmission of respiratory diseases, although it is not the only factor involved. It has been stated¹⁴⁰ that the spread of certain diseases such as measles and smallpox, and the 1918 influenza epidemic, stretched the theory of contact (or droplet) infection to the breaking point.

For a complete discussion of the many phases of the subject of the aerial dissemination of infection, including air-borne diseases of plants, and pollen allergies, reference may be made to the recent symposium on Aerobiology.^{1a}

Introduction of Microorganisms into the Air

Particulate matter is dispersed in the air from its source in two ways: by dynamic projection and by air carriage.¹⁰⁶ The sources of atmospheric contamination with pathogenic aerosols are infected organisms or their products. In man, the most important place of origin of such aerosols is the respiratory tract. The infective agents of the respiratory diseases are ordinarily contained in the secretions and discharges from the respiratory tract of the person having the disease, and are "atomized" into the air in the process of sneezing, coughing or talking. The agents of certain animal diseases may be given off in a similar manner. Desquamation, or scaling off of the skin in certain diseases, also may give rise to infective aerosols. "Dust" may contain large numbers of microorganisms of human origin which can remain viable for long periods of time. Dust also may be the source of infection of various organic, non-living materials. Many plant diseases are caused by molds, which produce large numbers of reproductive spores that are readily air-borne. Pollen grains, which are involved in reproduction in higher plants, are given off when the male reproductive structures of the flower are mature.

In relation to *human* diseases, infective aerosols must be studied chiefly in the semi-enclosed spaces of human habitation; aerosols infective for *plants* are found in the open air. These are the fields of intramural and extramural aerobiology respectively.

Infective Aerosols from Respiratory Activities. "In sneezing, coughing, and talking, droplets of saliva and other secretions, containing microorganisms, are expelled into the air. These droplets, particularly in diseases of the respiratory tract, constitute a potential source of infection. The larger particles are deposited onto nearby objects or fall to the ground before they can dry, although subsequently they may evaporate and their residue be lifted into the air as dust. Smaller droplets evaporate before reaching the ground, thus leaving their content of microbes suspended in the air. Such air-borne 'droplet nuclei' ²¹⁷ may remain in suspension for long periods of time and be carried long distances. The aerial transmission of infection, therefore, is possible in two ways, depending upon the size of the infected particle, namely, by droplets proper and by air-borne droplet nuclei. Although droplet infection has long been recognized, experimental evidence in support of strictly air-borne infection has, until lately, been lacking." ¹¹⁸

Previous work on the production and physical characteristics of respiratory drop-

lets, together with the writer's investigations of the atomizing of mouth and nose secretions into the air as revealed by high-speed photography, have recently been reviewed in detail.¹¹⁸ Therefore, only a few of the outstanding points will be summarized here.

In connection with the interpretation of studies on respiratory droplets, the question of the technique employed is significant, since many techniques *disproportionately underestimate* the numbers of smaller particles. This was an important reason for the inability of earlier investigators to demonstrate appreciable numbers of bacteria in the air. Particles usually have been captured by settling, by impingement, or by filtration. The particles may be caught on glass slides and the actual droplets counted, or in a liquid medium or on agar and the resulting colonies of bacteria enumerated. Animals,²²⁶ and the chick-embryo technique²⁹ have been employed to demonstrate virus particles. These methods and some of their limitations have been discussed by several authors.^{22, 44, 49, 73, 112, 118, 148a, 149, 160, 216, 230, 234, 245} Recently, photographic methods have been used to study respiratory droplets during and immediately after their expulsion.^{21, 117, 118, 119, 121, 205, 244}

The number of actual droplets obtained from a cough, or from speaking for a few minutes or enunciating letters, particularly consonants, varies from a few to a few hundred.^{80, 81, 82, 89, 92, 118, 125, 131, 155, 195, 196, 244, 252} In speaking, the greatest amounts of spray are given off in enunciating consonants like *p*, *t*, and *f*.^{89, 118, 125, 252} In sneezing, much larger numbers of droplets are produced than in coughing or talking.^{21, 117, 118, 119, 236, 244} Photographically, up to 40,000 particles per sneeze have been demonstrated (see Fig. 1), and 20,000 are common;¹¹⁸ up to 100,000 bacteria per sneeze have been recovered by bacteriological methods.^{21, 21a, 218} It appears that much greater numbers of droplets are produced than has previously been supposed, particularly in sneezing. In both stifled and unstifled sneezes, the *number* of par-

FIGURE 1. Introduction of micro-organisms into the air—a violent sneeze. High-speed photograph (exposure 1/30,000 of a second) showing the droplets during their evaporation to air-borne droplet nuclei (aerosols). Over 40,000 particles are shown. Many of the droplets were out of sharp focus, thus producing images much larger than actual droplet size. The actual diameter of many of the droplets depicted is about 10μ . A few droplets may be seen coming from the nostrils.

ticles issuing from the nose usually is meager compared with the number expelled from the mouth, while the *size* of the former is greater than that of the latter.¹¹⁸ This is of interest in relation to *air-borne* infection, since it is the *small* droplets—those originating chiefly in the mouth—which evaporate while in suspension in the air. For an interesting note on the appearance in three human generations of an atypical pattern (double sneezes) of the sneezing reflex, see ⁷⁶.

The number of bacteria expelled in respiratory droplets seemingly is at least equal to the number of even finely-atomized droplets.¹⁰⁹ Specific pathogenic bacteria usually are present in respiratory droplets in relatively small numbers compared with the total number of droplets and with the numbers of other organisms.^{18, 47, 91, 92, 108, 162, 191, 198, 258} Unpublished experiments by the author give the average number of bacteria in human saliva, which are cultivatable on nutrient agar, as about 6,000,000 per cc; up to 50,000,000 per cc may be found.

The horizontal distance to which the great majority of particles from the respiratory tract are actually expelled before they hit the ground or evaporate is not over 2-3 feet, as shown by the early work cited (see ²⁵²), and by later studies,^{41, 92, 109, 117, 118, 180, 185, 195, 196, 244} although a few large droplets or masses may be projected up to 10-12 feet.¹¹⁷ Certain mathematical calculations of the distance of projection of sneeze droplets have recently been made,¹⁰⁶ based on an initial velocity of 152 feet per second.¹¹⁷

The manner in which droplets are formed, that is, the mechanics of the "atomization" of liquids, is intimately related to the size, velocity and subsequent behavior of the particles. In coughing, sneezing and talking, droplets are formed by air-stream atomization, in which air at high speed is passed over the surface of the secretions, and the liquid is violently torn by the air-stream. Most sneeze droplets appear to originate from secretions present at the front of the mouth, more and smaller ones being produced when this orifice is restricted,^{117, 118} A diameter of about 10μ is the minimum droplet size producible from *water* atomized in a high-speed air-stream (100 meters per second and above).³⁶ Saliva and nasopharyngeal secretions are more viscous than water ^{143, p. 83, 197, p. 486}; and consequently can be atomized less finely under the same conditions.

The air pressures and velocities produced in respiratory activities are related to the number, size, velocity, distance of expulsion, and evaporation of droplets. In "loud" speaking, air velocities up to 16 meters per second have been found.¹⁹⁵ According to one report,⁴³ the velocity of air past the glottis in coughing may reach 100 meters per second. Sneeze droplets with an initial velocity of over 152 feet per second have been photographed.^{117, 118} Such a velocity, particularly for the smaller droplets, will produce almost instantaneous evaporation to their ultimate size.^{118, 217} Because of their viscosity, and in spite of the high velocities recorded, it is improbable that in respiratory activities droplets as small as 10μ in diameter are *originally* formed.¹¹⁷

Droplet size largely determines the physical behavior of droplets after expulsion, and involves several interrelated factors such as velocity, surface tension, viscosity, chemical composition, particulate inclusions, and evaporation of the droplets. Droplet size has usually been determined from measurements on glass plates upon which the particles settle or impinge. For physical reasons the smallest particles must be poorly represented, if at all, in samples so obtained. Such measurements of particle size *in the air at the time of collection* of droplets produced in *talking and coughing* show the range of diameter to be from about 20μ to $2,000\mu$, with a majority between perhaps 100μ and 500μ , and appreciable numbers below 100μ .^{11, 109, 155, 195, 196, 218}

Measurements of *sneeze* droplets on high-speed photographs show that many evaporate at least to 7- 10μ in diameter within a fraction of a second after expulsion,¹¹⁸ which particles would be among the smallest of air-borne droplet nuclei. The same technique shows that droplets produced in coughing and in talking are in

general somewhat larger than those resulting from a sneeze. These studies demonstrate that a higher proportion of *small* droplets are produced in respiratory activities than has hitherto been supposed. Particle size is of importance not only in relation to the state of suspension of particles, but also as regards their inhalation and other processes concerned in their removal from the air.

Experimental studies on droplet dynamics are meager; some general aspects have been considered.^{20, 86, 106, 240} The final size of atomized droplets depends upon the original size and upon subsequent evaporation; the latter is determined by several interdependent factors, some of which have been discussed in relation to respiratory droplets.²¹³ Both the kind and amount of dissolved substance have been shown to alter markedly the rate and degree of evaporation of minute droplets.²⁰⁷ It is probable that the final size of droplets is about that of the included bacteria or other particles.²¹³ Wells²¹⁷ has discussed the basic principles of the formation of "droplet nuclei" from droplets proper, particularly in respect to the time of, and distance to, evaporation of droplets. The life of small droplets in unsaturated air is much shorter than their time of fall if they settled without evaporation. Droplet size²¹⁷ and velocity in respect to the air¹¹⁸ are of predominating importance as regards evaporation, while air temperature and humidity have a relatively smaller effect.²¹⁷ Wells²¹⁷ concludes: "Somewhere between 0.1 and 0.2 mm lies the droplet size which identifies droplets of mouth spray that reach the ground within the life of the droplet as against droplets that evaporate and remain in the air with attached infection."

It is hardly necessary to offer proof that individuals with respiratory disease harbor the causative organisms in their respiratory tract. It is perhaps more significant to mention that many otherwise "normal" individuals, *i.e.*, without disease symptoms, carry pathogenic microbes in their nose and throat and on the skin.^{34, 59, 92, 94, 96, 104, 116, 144, 147, 152, 200, 257} These organisms may be expelled even in ordinary respiratory activities. The presence of such normal "carriers" in hospital wards and other situations appears to be an important source of infective aerosols,^{4, 5, 47, 136, 137, 151, 255} since weakened hospitalized persons tend to be more susceptible to infection. That infective aerosols may be given off from the respiratory tract of certain animals is evidenced from investigations on psittacosis (parrot fever),^{150, 194} canine distemper,⁶⁷ and tuberculosis in rabbits.²²⁹

Infective Aerosols from Other Sources. The production of aerosols from the scaling off of skin has long been recognized. An example quoted by Alexander^{3, p. 408} is the observation in 1868 by Dr. James Ross of epidermal scales from a case of confluent smallpox. In a beam of sunlight ("Tyndall beam" effect²⁰⁸) many scales were seen to remain in suspension in the air. Desquamation is also produced in other diseases, and even from normal skin, although strict proof of air-borne disease thus caused is lacking. Certain bacteria have been found in large numbers in the air about patients with burns infected with the same organisms,⁵¹ presumably having been given off from the infected area.

"Dust," which is a heterogeneous mixture of organic and inorganic, dead and living particles, becomes suspended in the air through movement, such as dry sweeping or heating. Many studies,^{4, 24, 48, 93, 113, 114, 162, 198a, 209, 212, 246, 248, 255} to mention a few recent ones, particularly of dust in hospitals, show infective aerosols to be present in dust from floors, and from bedclothes and the skin and clothing of infected persons. Some of such dusts consists, of course, of dried, settled particles from respiratory activities. The length of survival of microorganisms in dust varies greatly with the type of organism and with environmental conditions such as light, temperature and humidity;^{27, 28, 48, 114, 191, 248, 255} some bacteria may remain alive for years.

Obviously, dust containing various microorganisms may also be the source of infection of non-living materials such as food products,⁹ textiles, etc., which contain some moisture and food for the microbes. One study has been made of the contami-

nation of the air of textile mills by evaporation of droplets of contaminated water used for humidification, and from manipulation of the fibrous material being processed.²³⁴

The dissemination of many plant diseases by air-borne spores of the invading mold is well recognized.¹⁹³ The parasite may be superficial or otherwise; in either case the reproductive spores are usually produced on the surface. Spores may be forcibly discharged into the air in various ways, as well as being passively released.¹²³ In some plant diseases spores are produced in astronomical numbers; it has been shown that various kinds of fungus spores may be carried hundreds of miles by air currents.⁴⁵ The inhalation of certain types of fungus spores may also produce allergic conditions in man.⁷⁰ Further discussion of this subject may be found^{45, 70, 123, 166, 193} in the symposium on Aerobiology.¹⁴

Pollen grains may be insect- or wind-borne. They are exposed in the flowers of higher plants when the male reproductive structure is mature. The pollens most commonly causing "hay-fever" come from various grasses and ragweeds, although other kinds of plants produce pollens to which some persons are allergic.^{253, 254}

Conditions of Suspension of Infective Aerosols

Particle size and air movement are the chief factors determining whether aerosols will remain in suspension or will sediment (physical stability). In addition, from the standpoint of infection, the type of organism and various environmental conditions determine how long the aerosols will remain alive and infective (biological stability or viability).

Presence of Living Aerosols in the Air. Under practical conditions it is not easily determinable what proportion of atomized respiratory droplets remain in the air as droplet nuclei or become resuspended as dust, but the aggregate may be large under certain conditions. Many investigators, particularly during the past twenty years, have isolated from air not artificially contaminated, considerable numbers of air-borne bacteria characteristic of the respiratory tract^{24, 30, 31, 52, 60, 71, 97, 102, 104, 115, 137, 138, 139, 161, 162, 186, 191, 198a, 236, 240, 248, 251}; also references in²³¹. These nasopharyngeal organisms have been found to be most prevalent in the semi-enclosed spaces of human occupancy, such as schools, hospitals, institutions, and the like, their numbers being roughly proportional to the degree of occupancy and activity and to the amount of respiratory infection. Usually the numbers of pathogenic bacteria are small in comparison with the total air flora.

A few thousand bacteria per 10 cubic feet of air were reported in a room in which sneezes were artificially induced in the occupants.²³⁶ In other occupied spaces—schools, theaters, subways, hospitals—under a variety of conditions the total numbers of air-borne bacteria recoverable by the Wells centrifuge²¹⁶ have been found to be up to a few hundred per 10 cubic feet of air, with nasopharyngeal organisms present in larger numbers than has previously been thought.^{31, 137, 138, 139, 161, 186, 231, 236, 240} It is obvious that the dilution of bacteria in air, particularly with artificial ventilation, is important in relation to quantitative air bacteriology. In outdoor air the total numbers of bacteria are in general much less than in indoor atmospheres,^{240, 251, 259} although some have been found at altitudes of 4-5 miles.¹⁶³⁻¹⁶⁶

Fungus spores also are widely distributed throughout the atmosphere. For aerial mold spore surveys, see^{16, 45, 70, 148}. Numerous studies of the prevalence of pollens in the air have been made.^{49a, 55, 68, 253}

Physical Stability of Aerosols. The settling of aerosols is of practical importance, even in still air, only when the diameter of the particle exceeds about 10μ .⁸⁶ That particles less than 10μ in diameter result from respiratory activities, and that many mold spores and some pollen grains are smaller than this has been mentioned above. Air movement will, of course, keep particles much larger than this in sus-

pension for varying periods of time. (For methods of sampling air bacteriologically, see ^{22, 29, 44, 49, 73, 112, 148a, 165, 178, 216, 226, 245}; for sampling of air-borne pollens, fungus spores and insects, see ^{49, 69, 70, 87, 106a, 165, 253, 254}.)

It is demonstrable that a proportion of atomized infected droplets may be carried for long distances by air currents, and the bacteria remain alive. This was recognized by the earlier investigators,²⁵² and later studies have confirmed it.^{41, 48, 135, 153, 234, 236} Living aerosols may be disseminated through mechanical ventilating systems^{57, 110, 170, 234}; (see also references in ¹⁸⁸). The length of time that aerosols will remain in suspension in *still* air may be estimated from Stokes' Law.^{62, 159, 217, 230}

It is technically difficult to determine experimentally the true settling rates of living aerosols, since the cultural methods used give an apparent rate which may be influenced by the death of the organisms. Apparent settling rates of infective aerosols have been measured in closed chambers, using finely atomized suspensions of bacteria representing droplet sizes that are produced in respiratory activities. Settling appears to be at a rate which decreases geometrically, and much of the material remains in suspension for many hours. Using a resistant organism, and with a mean droplet diameter of about 120μ , it was found that after the immediate settling of the heavier material and evaporation of the remainder, the material disappeared from the chamber at a rate, including the death rate, of 7 per cent per hour over a 24-hour period.²³⁵ As measured by the development of colonies upon agar plates, short-chain alpha hemolytic streptococci in droplets of a mean diameter of 10μ deposited about 22 per cent of its ultimately settleable particles during the first hour of suspension in the dark in a room 8 feet high. About 16 per cent of the initial number remained suspended for over 8 hours. As calculated from the settling rate, two-thirds of this evaporated material was less than 1.34μ in diameter, and 95 per cent of it less than 2.68μ .^{159, 160} "It represents, therefore, exactly that state of suspension in which sanitarians are most interested; that is, particles of the sort produced by sneezing large enough to carry bacteria and so small that the aerial life is measured in hours rather than minutes."¹⁵⁹ The apparent rate of settling (including the death rate) of vaccinia virus in the dark is about twice that of streptococci.²⁹ Probably this greater rate of disappearance is largely accounted for by a higher death rate.

A bacteriological study of the settling rates of natural sneeze droplets in an experimental room showed that of the total recovered, 20 per cent of the particles remained suspended for 15 minutes, and 4 per cent for 30 minutes.^{21a}

One investigator,¹⁴⁵ exposing culture plates in an operating room during operations, estimates that 30,000-60,000 viable bacteria may fall on the "sterile" field of operation in an hour. Other studies ^{7, 98, 102, 104, 140, 156, 215} show varying numbers of bacteria present in and sedimenting from the air of operating rooms. The numbers are much higher in winter (due presumably to the greater incidence of respiratory infections) than in summer; when the room is occupied than when unoccupied; and in rooms not air-conditioned.^{98, 104} The relation between the number of bacteria settling out of the air, and those remaining suspended, has been studied in a textile mill.²³⁴ Other data on the size and settling of infective aerosols may be found in ²³³. For settling rates of fungal spores, see ⁴⁵.

As indices of the bacterial pollution of air by human beings, streptococci,^{89, 218, 231, 232, 233, 238} *Neisseria catarrhalis*¹²⁰ and *Staphylococcus aureus*¹⁰⁴ have been suggested. Streptococci have been studied most thoroughly in this regard.

Viability of aerosols in normal air. The viability of aerosols is of outstanding significance as regards air-borne infection. Controlled experimental studies on this point are rather meager. It is apparent that any type of bacteriological air-sampler partially simulates conditions of possible human infection, in that only those aerosols which are viable will be enumerated by the methods.

There is a general agreement that many bacteria and viruses—including such

respiratory forms as influenza virus, streptococci, pneumococci and diphtheria bacilli—may remain alive in "normal" air for hours.^{26, 27, 28, 29, 33, 159, 192, 226, 227, 235} The death rate increases at higher temperatures.²⁷ The effect of humidity on the death rate is difficult to separate from its possible effect on the settling rate, and has not been clearly shown. Some investigators^{184, 204} believe that microbes survive longer in humid than in dry air; others²³⁴ claim the reverse to be true. Survival of streptococci and pneumococci at least, is much longer in the dark than in the presence of sunlight, diffuse daylight, or illumination from fluorescent lamps,^{26, 28} survival in the dark being measured in days, and in light in minutes or hours. Even ordinary daylight appears to be a more potent lethal agent for microorganisms than has been generally recognized. The relation between light intensity and lethality appears to be linear. Influenza virus suspended in air has been found to remain viable for at least an hour in the dark,²²⁶ and vaccinia virus for eight hours.²⁹ Influenza virus is rather resistant to drying, and can be demonstrated in dust.⁷² Not only may pathogenic bacteria remain *alive* in air for days, but their *virulence* (infectivity or disease-producing power) likewise appears not to decrease.^{32, 33, 248} The viability of pathogenic aerosols under the influence of specific lethal agents will be discussed in the next section.

Spores of various fungi causing plant diseases, despite the many unfavorable conditions during transit, do survive the vicissitudes of wind dissemination.⁴⁵

From the foregoing it is apparent that air-borne living entities, on the order of a few microns in size, do exist. Aerosols of less than 10μ diameter are physically very stable even in still air,⁸⁶ and under conditions of normal air movement much larger particles will tend to remain in suspension. Aspects of particle size in relation to inhalation by man, particularly as regards the removal of particles in the respiratory tract, have been considered by^{106, 130, 185, 213, 230}

Control of Infective Aerosols

A number of methods are available for the control of pathogenic aerosols and thereby of human air-borne infection. Among the techniques are the use of masks; spatial separation, including mechanical barriers, of infector and infectee; ventilation and air-conditioning, including dilution and filtration; keeping down dust; irradiation of air with ultraviolet light, including light barriers; and the use of germicidal sprays. Generally speaking, the practical application of these methods has lagged, perhaps largely because the necessity for the control of air-borne microorganisms has only lately become apparent. Recently attention has been given to the control of air-borne infection in air-raid shelters and similar situations.⁶

As regards the control of aerosols infective for plants, destroying infected plants and their sources of infection have been practiced. Attempts have been made in some communities to control the pollen of ragweed, in particular, by destroying the plants. As a practical matter, however, this method of trying to prevent "hay-fever" is of rather questionable merit, because of the long-distance dissemination of pollen from other sources.

Masks. Masks *tend* to prevent the introduction into the air of particles from the respiratory tract. Protection of patients against direct expulsion of nasopharyngeal organisms by the use of masks during operations is now common surgical practice. Less common is their general use in hospitals and elsewhere to protect debilitated patients, particularly children, from the nasopharyngeal flora of the attendants.¹⁵¹

Masks are most commonly employed to prevent the *expulsion* of droplets rather than the *inhalation* of dried droplet residues. The various types of fabric masks in common use differ greatly in their permeability to air and to particulate matter, as shown by tests using the air volumes and pressures involved in respiratory activities.¹¹⁸ We have found this range of variation for air passage to be about 10-fold in terms of *volume* of air passed through the fabric per unit area per unit time at

constant pressure,¹¹⁸ which corresponds to an average of a 60-fold variation in resistance to air flow (pressure-drop across the fabric) at constant volume. Experimental tests of the efficiency of such face masks against droplet expulsion reveal that varying numbers of respiratory particles pass through the fabric or around the edges of the mask.^{10, 17, 85, 118, 124, 134, 151, 168, 187, 202, 214} Deflector masks prevent only direct droplet expulsion, not air-borne particles.^{118, 187} Clinical observations also suggest that many types of masks are not entirely adequate to prevent the transmission of infection.^{58, 59, 96, 100, 104, 137, 145, 151} Hence, as has been stated,¹⁵¹ the adequacy of the mask must be viewed with scepticism, although some types are over 90 per cent efficient under stringent test conditions.^{118, 187} It is apparent that great comfort in the wearing of a mask, together with high filtering efficiency, are very difficult to attain. Extra heavy masking of operating room personnel who are "carriers" of pathogenic bacteria in the nose and throat will reduce the number of aerial microbes and the incidence of post-operative wound infections.^{47, 59, 96, 144, 145, 214}

Ordinary face masks sometimes are used as a protection against the *inhalation* of infective aerosols. The efficiency of such masks *as usually worn* probably is low, due in part to the fact that they do not fit tightly around the face. (For numerous other references on masks and masking, see ¹⁵¹.)

Separation of infector and infectee. This type of control may be essentially a diluting of the aerosol in the air, or may be based on preventing or directing the dispersal of the infective material or even upon destroying it. The so-called barrier method of nursing, or bed isolation, has been used in contagious disease hospitals for years. The barrier may be air (spatial separation), some type of solid screen, or, more recently, screens of ultraviolet light. Barriers have been employed in infants' hospitals and similar situations, each patient being placed in a separate cubicle. The early success of some of these methods in contagious disease hospitals was taken as evidence for the contact theory of infection; undoubtedly the methods do help in preventing contact. A few examples will serve to indicate the methods used and the results obtained.

By allowing more space between beds in dormitories where a number of persons sleep in the same room, the incidence of certain respiratory diseases can be decreased.^{52, 64, 66, 71, 88} Likewise, in hospitals where contagious disease is present, cross-infections are fewer when the beds are farther apart.^{94, 189, 255} This presumably is due in part at least to a diluting of the air-borne microbes. However, some diseases of respiratory origin cannot be controlled by simple spatial separation.

Preventing or directing the dispersal of infective aerosols may be accomplished in some measure by placing patients in separate cubicles.^{5, 23, 58, 75, 151, 176, 188, 255} These cubicles may or may not have a common air supply; ultraviolet light recently has been used in conjunction with such cubicles for infants. Bacteriological air-sampling in cubicles shows that mechanical barriers alone prevent to varying degree the dissemination of living aerosols. The principles of the control of cross-contamination by the use of mechanical barriers, and the application to a positive-pressure cubicle system for infants,¹⁸⁸ and to the rearing of germ-free animals have been discussed by Reyniers.^{173, 174, 174a}

Separate incubators, each with its own supply of circulated outside air, have been employed with good results to protect premature infants against infection.^{39, 40} Various methods of control of aerial respiratory contagion have been studied under controlled conditions at the Cradle, an adoption nursery at Evanston, Illinois.^{50, 188} Here, as elsewhere,^{23, 53, 176} it appears that mechanical barriers (cubicles) alone are a less efficient means of preventing the aerial dissemination of microorganisms than when used in conjunction with air-conditioning or ultraviolet light. Ultraviolet light screens alone have given encouraging results. (For further discussion of control by ultraviolet radiation, see below.)

Ventilation and air-conditioning. While it is generally assumed that the bacterial pollution of occupied rooms may be greatly reduced by dilution with clean outside air, certain studies do not entirely confirm this view.^{110, 256} The number of living aerosols may actually be increased by stirring up infected dust particles off the floor, or from inside the ventilating system. Much depends upon the air-distribution system used, the number and activity of the occupants, and the general cleanliness of the room. The direction of air flow into the room should be transverse or upward, not downward.²⁵⁶ Improper air flow into a room may more than offset any advantage gained by filtering the air. Under proper conditions, however, ventilation, particularly with air-conditioning, may reduce the numbers of suspended bacteria in occupied rooms.^{52, 97, 98, 188, 256}

Commercial air filters, particularly if treated with a viscous oil, and air-washers, are fairly efficient (40-80 per cent) in removing bacteria,^{56, 256} although the effectiveness of filters in actually reducing the bacterial population in occupied rooms is small or nil.²⁵⁶ Filters are also effective for pollen. For a method of testing filters against pollens, bacteria and molds, see⁶³.

The measurement of sanitary ventilation has been discussed by^{231, 232, 233, 237, 240}.

Control of dust. As mentioned previously, dust contains large numbers of microorganisms which may remain viable for long periods of time. Dust becomes re-suspended in the air through movement, such as sweeping or the activity of the occupants of a room. Many studies have shown the relation between activity and the number of living aerosols, hence keeping down dust particles is hygienically important. The treatment of floors and bed-clothes with mineral oils, to reduce dust-borne bacteria, has recently been advocated,^{198a, 199, 209, 210, 211, 212, 246} as has the treatment of floors in breweries to prevent infection of beer.⁹

Radiant disinfection of air. In recent years irradiation of air with ultraviolet light, as a method of controlling living aerosols, has been rather extensively studied, both experimentally and under practical conditions in hospital wards and operating rooms, nurseries, and schools.

Fundamental aspects of the action of ultraviolet light on microorganisms, including those suspended in air, have been discussed.^{65, 74, 84, 111, 126, 132, 133, 137a, 171, 172, 190, 221, 222, 227, 236} For many kinds of bacteria and fungus spores the most lethal wavelength is close to 2650 Å; exact data for viruses infective for human beings are lacking. Bactericidal action falls rather sharply, although not uniformly, on either side of this peak to about 2300 Å on one side and 3000 Å on the other. The activity rises again below 2300 Å, although this lower region has been investigated but little in this regard. Bacteria, fungi and some viruses can be inactivated by radiation between 3400 Å and 4400 Å. The mechanism of inactivation in this range is apparently of a different nature from that of killing produced by radiation below 3000 Å.¹¹¹ Wavelength 2537 Å, which is emitted most intensively by the low-pressure mercury vapor lamps commonly used for many practical purposes, is close to the maximum of sensitivity of bacteria.

The amount of radiant energy, time, distance, velocity of air movement, etc., are factors which must be considered in bactericidal irradiation of air.^{137a, 221, 236} Different types of bacteria vary, although often relatively little, in their response to ultraviolet radiation;¹¹¹ with proper energy output a few moments exposure may be lethal within a short distance. It is possible to show, however, that a given species of bacteria is not equally resistant to ultraviolet radiation throughout its life span.¹⁷² Bacterial sensitivity is influenced but slightly by temperature within ordinary ranges,⁸⁴ although surviving irradiated organisms may show increased sensitivity to heat⁵⁴ and to disinfecting agents. The intensity of radiation multiplied by the time of exposure is a constant for a certain percentage of killing.^{126, 171, 172} With bacteria suspended in air, some investigators have found ultraviolet to be more

lethal in dry air,^{126, 137a, 221, 222, 236, 247} while others¹⁷¹ claim that this effect is more apparent than real, the seeming difference in resistivity being due to the selectivity of the bacteriological sampling device.

In the use of ultraviolet radiation in occupied rooms, its physiological effects on the persons exposed must be considered. These effects include photosensitization, action on the skin and eye, on wound healing, and several others.^{19, 128, 132, 153} In the operating room the skin and eyes of the personnel can be adequately protected, while still supplying radiant energy sufficient to kill infective aerosols.^{95, 97, 99, 100, 102, 128} It appears established that ultraviolet light of low intensity stimulates wound healing,¹⁵³ although higher intensities are injurious in various ways.¹³² Hence, in radiant sterilization of air in the operating room, it is essential that exposed wounds are not subjected to destructive intensities of light. Studies in this regard,^{100, 102, 103, 105, 127, 128} show that air sterilization can be accomplished without producing any deleterious effects on the patient, such as adhesions, abnormal temperature, or slow wound healing.

The production and control of bactericidal radiation, the characteristics and standardization of lamps, and considerations in the design of ultraviolet sanitation equipment for air sterilization, have been discussed by several authors.^{35, 46, 100, 128, 129, 137a, 169, 183, 224, 225}

The ultraviolet irradiation of air in operating rooms has been shown to bring about a great decrease in the number of living aerosols, and in the incidence of post-operative infections^{74, 95, 97, 98, 99, 100, 101, 102, 105, 127, 128, 175} without evident harm to the personnel or patients. In one hospital,¹⁰⁰ for example, post-operative infections were reduced to from $\frac{1}{20}$ to $\frac{1}{400}$ of the previous number, largely by this means. Some opinion holds, however,^{7, 8, 59, 215} that transmission of bacteria by other than air-borne means is chiefly responsible for post-operative infections, and that the benefits of bactericidal irradiation of air in this regard are over-rated.

Studies of the efficacy of ultraviolet light screens between cubicles, and of irradiation of the general air of wards and corridors in children's hospitals and nurseries, show that pathogenic aerosols can be greatly decreased by such methods. Concomitantly, there is a drop in the number of cross-infections and in the incidence of respiratory diseases.^{14, 15, 23, 58, 90, 175, 176, 188, 246} Similarly, in a school,^{239, 242, 243} the spread of several epidemic diseases was checked among highly susceptible groups of children by radiant disinfection of the air.

Recent quantitative studies^{26, 28} indicate that sunlight and ordinary daylight probably play an important role in the suppression of streptococcal and other infections of the respiratory tract, through their potent action on infective aerosols. The region 3400-4400 Å is very intense in sunlight,¹¹¹ and is an important factor in the low survival of infectious agents in the outside air.

Within the last few years, ultraviolet light has been used in connection with the storage, processing, and packaging of various foods, in order, among other things, to prevent their infection by air-borne microorganisms.

For general articles on air-borne infection and its control by irradiation of air, see^{182, 219, 223, 224, 225}

Germicidal aerosols. Although the idea of using germicidal mists and vapors for air sterilization dates back to Lister, until recently they have had little use, since most of the agents which have been previously employed are toxic or irritating to human beings. The literature has been reviewed.^{10a} Experimental evidence on the disinfecting power of non-irritating aerosols is now available,^{179, 207, 250} but little practical application has as yet been made of the data.

Among recently investigated compounds which appear to fulfill the desiderata of a germicidal aerosol, namely, good killing power for microorganisms, cheapness and availability, and lack of toxicity for human beings, are sodium hypochlorite, hexylresorcinol, propylene glycol, and triethylene glycol. Sodium hypochlorite has been

investigated by several workers.^{11, 12, 21a, 61, 141, 142, 167, 203, 207} One gram of 1 per cent NaOCl atomized in as much as 40,000,000 cc of air will effect sterilization;^{141, 142} 1 gram of 2 per cent NaOCl in glycerol-water to 6,000,000 cc of air was found highly effective by other investigators.¹⁶⁷ One very effective aerosol developed in England contains 10 per cent hexylresorcinol and 0.05 per cent alkyl sulfate, "Lorol,"* in alkaline propylene glycol;²⁰⁷ one gram of this in 4,000,000,000 cc of air is bactericidal.

Propylene glycol alone has been investigated as a germicidal aerosol rather thoroughly, both as to its bactericidal activity and its toxicity for human beings.^{178, 179, 180, 181} In addition to its other desirable characteristics, this material is odorless and tasteless. Its toxicity for man is very low, but for microorganisms very high. One gram of glycol vapor in three to four million cc of air effects immediate killing of staphylococci, pneumococci and streptococci.¹⁷⁹ Rapid but not immediate sterilization occurs in considerably higher dilutions. The above concentration also protects mice from influenza virus.^{107, 181} Other members of the aliphatic glycol series have recently been investigated as regards their bactericidal and viricidal action.^{181a} Triethylene glycol, in particular, compares favorably with propylene glycol as a germicidal aerosol. The mode of action of glycol on bacteria has been discussed by^{179, 180,}; glycol *aerosols* (mists) can be replaced by glycol *vapor* with equally effective results.

Hydrogen peroxide has been suggested as a germicidal aerosol,¹ but its use in this regard has not yet been thoroughly investigated. Ozone, in concentrations which can be breathed without irritation by persons for long periods of time, cannot protect against air-borne infection.^{72a}

Methods for the production of aerosol mists, and detailed studies of particle size and evaporation may be found in²⁰⁷.

Certain kinds of smokes have been proposed for air sterilization.^{79, 206} Incense smoke and smoke from ignited cardboard soaked with potassium nitrate were found to be highly effective. It is reported that 1 gram of the chemical substance dispersed in smoke form in 500,000,000 cc of air causes destruction of 95 per cent of air suspended bacteria within 15 minutes.* According to some investigators¹³ germicidal aerosols, and particularly smokes, show an increase in their lethal effects with increased humidity; other workers find the opposite.^{243a} Apparently the effects of humidity have not yet been properly evaluated.

The practical applications of germicidal aerosols to air sterilization have as yet been few. It is stated^{21a} that the British Ministry of Health proposes to issue sodium hypochlorite sprays for use in London air-raid shelters. Sodium hypochlorite has been used in factories and offices, and it is reported^{141, 142} that there is a marked diminution in the air-borne bacteria and a decrease in the incidence of acute respiratory infections in the population exposed to the mist. Other investigators⁵³ report the successful use of an aerosol in controlling the spread of streptococcus infections in a hospital ward, after the usual measures had failed. In an investigation recently reported,^{93a} a great reduction in the incidence of respiratory infections was found in a convalescent ward during a period of vaporization of propylene glycol in the ward.

From the preceding discussion it is evident, first, that the bacterial content of the air of certain occupied spaces can be greatly diminished by suitable control measures, and second, that this control results in a lower incidence of respiratory infections and in fewer post-operative wound infections. Since the bacteriological control of

* "Lorol" is the sulfuric acid ester of mixed fatty alcohols derived from coconut oil.
J. A.

† This raises the question as to the bactericidal effect in churches of incense and other "burnt offerings," and brings to mind the lines of William Cowper:

"God moves in a mysterious way
His wonders to perform."
J. A.

air decreases disease incidence, one must conclude that air is a vehicle of infection, although not necessarily the only means of spread.

Infective Aerosols and Disease

As yet it is not possible to evaluate fully the *relative* importance of strictly air-borne transmission and of direct contact (including droplets proper) as modes of spread of infection, particularly human respiratory infection. The hypothesis that respiratory infections are largely air-borne is newer, and is considered by some investigators, particularly Wells,^{236, 239, 240} to be more satisfactory than the older theory that these diseases are spread by direct contact. Recent work offers much support to the former hypothesis, and this evidence for the actuality of air-borne infection in certain situations at least, cannot be ignored. On the other hand, much of this evidence, while supporting the air-borne hypothesis, does not necessarily invalidate transmission by direct contact.

The evidence has been adequately reviewed by several investigators,^{25, 186, 236, 240} and the various aspects of the subject formed the basis for a recent symposium on aerobiology.^{1a} As has been pointed out,²⁵ the evidence is based on three rather distinct lines of research: first, laboratory studies and surveys of the presence, distribution and survival of respiratory organisms in the air; second, the control of infections by measures designed to rid the environment of pathogenic aerosols; and third, investigations of the bacteriology and epidemiology of experimental air-borne infection, and of respiratory infections in hospitals and other institutions. The first two of these lines of evidence have for the most part been discussed above; the third, and certain aspects of the others will be considered below. As a background we shall first outline some of the interactions of the host and its invading microbe as they relate to infective aerosols.

Some interactions of microbe and host. Many factors are involved in the production of disease by infective aerosols, even after assuming that this is the only method of spread. The type of infective agent and its virulence, its concentration in the air and the amount inhaled, the fate of the organisms in the respiratory tract, and the resistance of the host are some of the chief considerations. Only a few outstanding points in this regard can here be touched upon.

It is well known that different types or strains of the same microbe, as well as different kinds of microbes, vary in their disease-producing ability or virulence. It is possible experimentally to change the virulence of microorganisms. As a practical matter virulence tends to increase with the passage of the organisms through the animal body; in epidemics increased virulence is noticed as the contagion spreads through the population. Certain aspects of the virulence of bacteria in air and dust have previously been referred to.

Although in practice it may be necessary to use the concentration of bacteria in the air as a measure of sanitary ventilation, this number obviously bears little relation to the number inhaled, unless one considers the duration of exposure, the fate of the microbes after inhalation, and the type of organism in relation to that part of the respiratory tract which it must reach in order to produce an infection. Very little evidence is available concerning the number of organisms which must be inhaled to produce infection. Undoubtedly this will vary greatly with the type of organism and its virulence, and with the resistance of the host. In certain diseases at least, the survival period, the type, and progress of the ensuing disease are functions of the dose of naturally inhaled microorganisms.²²⁹ In the experimental production of air-borne tuberculosis^{229, 241} it was found that as few as 20 tubercle bacilli would produce the disease; tuberculosis was produced sooner, and was of a different type when greater numbers of the organism were inhaled. Experimental air-borne streptococcus infection of mice required several hundred organisms per mouse to

produce 18 per cent mortality in a group, while over 10,000 organisms per mouse resulted in about 90 per cent mortality.²⁴¹

The fate of microorganisms after inhalation is of evident significance as regards disease production. Suspended particles tend to be removed in the upper respiratory tract, whereas some diseases are produced only in the lower part of this system. The air passages are an important first line of defense^{200, 201} in this regard; not only may a large proportion of suspended particles be filtered out in the nose,¹⁸⁵ but the nasal secretions are also definitely inhibitory to some microorganisms.^{83, 200} Turbulence tends to throw inhaled particles out of suspension in the upper parts of the respiratory tract²¹³ where they may be removed by ciliary action.²⁰¹ Particles which reach the lungs tend to be removed or killed by phagocytes.¹⁷⁷

The subject of host resistance or immunity to infection is broad and complex, but only one or two points will be mentioned here. Both natural immunity and acquired immunity are part of the picture. There is great variation in susceptibility to the same and to different infections among different persons. The same person, also may vary greatly at different times in his resistance to a disease, depending upon physical condition and other factors. Hospitalized, weakened and debilitated persons are especially susceptible to infectious diseases, and children are in general more susceptible than adults. In this latter connection, it is worth noting that these are the groups on which most of the investigations of air-borne infection have been carried out.

Experimental air-borne infections. Air-borne infections have been produced in experimental animals under strictly controlled conditions which exclude contact infection, and which are quantitative as to dosage.^{220, 241} These infections include influenza and pneumonia,^{220, 228} tuberculosis,²²⁹ poliomyelitis,⁷⁷ and streptococcus infections.^{220, 241} In some of these cases it was demonstrated that the inhaled organisms were carried deeply into the lungs. Other significant observations as regards air-borne infection and its development were made in these investigations, but space does not permit their consideration here. The basic demonstration was that strictly air-borne infection is readily possible.

Infection of wounds. Another type of infection—that of the post-operative infection of wounds—apparently may be air-borne, although the introduction of the responsible organisms certainly is not limited to the aerial route. As mentioned previously, many persons are “carriers” of organisms pathogenic for other individuals, and the organisms may be expelled from the nose and throat even in ordinary respiratory activities. The number of “carriers” is particularly high in the winter, when the incidence of respiratory infections is greatest. The observed relation between such “carriers” among operating room personnel, and the incidence of post-operative wound infections,^{59, 96, 104, 145, 146, 214, 215} seems not to be fortuitous. This belief is strengthened by the fact, discussed under control of infective aerosols, that such measures as masking of “carriers” or their exclusion from the operating room, and irradiation of the air, can be shown to result in a decrease both in the aerial contamination and in the number of wound infections.

Hospital infections. The spread of diphtheritic, pneumococcic and streptococcic infections in isolation, children's and maternity hospitals are well-recognized problems.²⁵ The consensus is that while direct contact is undoubtedly a frequent mode of transmission in these cases, there is also evidence for air-borne spread. Concerning pneumonia, although there is evidence that pneumococci can survive in air and dust there is very little direct and positive proof of pneumococcal disease in man acquired through droplet or air-borne infection.⁷⁸

Streptococcic infections offer perhaps the most evidence for the hypothesis of transmission by the air-borne route. Streptococci are of different types which can be identified serologically, and it is often possible to trace infections by identifying

the person from whom a particular type is derived. The most significant studies have been carried out in the scarlet fever wards of isolation hospitals, where so-called complications or cross-infections are a major problem. Various studies in this regard^{5, 24, 25, 60} show that the majority of the complications are actually new infections caused by a strain of streptococcus serologically distinct from the patients' original one, and whose source can usually be traced to some other individual in the hospital. Up to 75 per cent of patients show the presence of new types in the throat after some time in the hospital,²⁵ although these new types do not always reproduce the disease. The bacteriological evidence for the air-borne transmission of these cross-infections is chiefly that ". . . streptococci are widespread in the ward air and the serological types identified were not confined to the neighborhood of patients infected with a particular type."²⁴ The possibility of direct or indirect contact infection was not ruled out in these cases; it was, in fact, often known to occur. The air-borne spread of streptococcal infections is strongly suspected in other hospital situations.^{25, 122, 154} Although there have been no extensive studies on the transfer of infection from patient to patient by nurses, it is observed that patients nursed in isolated cubicles show an almost negligible incidence of reinfection as compared with those treated in multiple-bed wards.²⁵ In infants' and children's hospitals where contact among patients is ruled out, and transmission from attendants to children is believed to be small, the decrease in the incidence of various infections by cubicle nursing and by ultraviolet irradiation of the air is evidence for the air-borne spread of respiratory contagion.^{15, 23, 58, 176, 188}

That the air-borne spread of diphtheria is bacteriologically possible is shown, for example, by the fact that the organism can be demonstrated in dust from the floor of wards.²⁵⁵ Further evidence for aerial dissemination was found in the fact that a number of patients nursed in cubicles showed no signs of reinfection, which is not what would be expected if attendants play an important part in the transmission of this disease.

The spread of epidemics. The epidemiological evidence for the aerial spread of certain diseases has been reviewed by²⁴⁰. Studies of the epidemic spread of respiratory diseases, particularly virus infections such as influenza, measles and chickenpox, indicate that their widespread occurrence almost requires the hypothesis of air-borne transmission.²³⁶ The velocity of spread, the rise and fall of the epidemics, and the epidemiological patterns manifested, are considered by some investigators²⁴⁰ to be more accurately explained by the air-borne than the contact theory. In a recent four-year epidemiological study of radiant disinfection of air in day schools in relation to the control of epidemic contagion,²⁴² epidemic spreads of measles were checked in three irradiated primary schools during the severest epidemic ever experienced by the city of Philadelphia.²³⁹ Evidence also was obtained for a lower incidence of chickenpox and mumps in irradiated rooms as compared with the unirradiated. One conclusion from these studies was that "Since the dynamic spread of epidemic contagion can be controlled by the radiant disinfection of air, it follows that air must be a vehicle of infection."²³⁹

Evidence for the production of plant diseases from air-borne fungus spores is given by^{45, 123}. The aerial transmission of many diseases of plants is unquestioned, since direct contact generally is not a factor.

It is apparent from the brief discussion above that the air-borne transmission of infection, both respiratory and otherwise, is an actuality, and is more important than has hitherto been recognized. As regards human respiratory diseases, the importance of this mode of spread relative to other means is yet to be delineated, but the significant fact is that it does occur.

Physical Chemistry of Lipides *

MONA SPIEGEL-ADOLF, M.D.

Professor of Colloid Chemistry, Temple University, School of Medicine,
Philadelphia, Pa.

Definition and Classification.

Peters and Van Slyke,⁷⁷ following the definition of Maclean,⁶⁸ describe lipides or lipins as "substances of a fat-like nature, yielding on hydrolysis fatty acids or derivatives of fatty acids, and containing in the molecule either nitrogen or nitrogen and phosphorus." The lipides can be divided into two groups: (1) phosphatides, which include lecithin, cephalin and sphingomyelin, in the first two of which N : P = 1, in the latter N : P = 2; and (2) cerebrosides, which do not contain phosphorus (but are distinguished by a carbohydrate group) include among others phrenosin and kersin.

The different solubilities of these substances in organic solvents is summarized in Table 1 (Bull¹²):

Table 1. Solubilities of lipides in organic solvents

| | Ether | Alcohol | Acetone |
|---------------|-------|---------|---------|
| Lecithin | S | S | X |
| Cephalin | S | X | X |
| Sphingomyelin | X | H | X |
| Cerebroside | X | H | H |

Structural Formulas. Most of the biological and physicochemical work done on lipides has been concentrated on the phosphatides, especially on lecithin and cephalin. General formulas of these substances follow:

Until recently the following formulas were generally accepted for cephalin:

* For complete treatise on this field see Bloor, "Biochemistry of the Fatty Acids and their Compounds, the Lipids," New York, Reinhold Pub. Corp., 1943.

In 1941 Folch and Schneider³⁵ showed that over half of the nitrogen of cephalin is not in ethanolamine but in a hydroxyamino acid which Folch³⁴ later found to be serine. Chargaff and co-workers,²² using isotope dilution methods and direct isolation,²¹ were able to confirm these results. Folch and Schneider³⁵ found that intact cephalin reacts with nitrous acid and with ninhydrin in a manner which indicates the existence of both free NH_2 and COOH groups. They assume therefore "that the hydroxyamino acid in cephalin is attached to the rest of the phosphatide molecule by ester linkage through the hydroxyl group."

Folch³⁶ claims that cephalin is not a single substance but consists of a mixture of inositol, phosphatidyl-serine and of a more unsaturated compound, which does not contain any amino acids. Chargaff, Ziff and Rittenberg,²³ using nitrogen isotopes, found that phosphatides from beef brain and lung contain considerable amount of amino acid nitrogen. There is much less in liver and heart, and egg-yolk phosphatides are free of amino acids. Storing of phosphatides seems to affect the content of amino acid nitrogen. It seems interesting in this respect that, according to Chalkoff and co-workers,³⁹ using radioactive phosphorus, different tissues (liver, brain, excised nerve) are able to form phospholipides *in vitro*.

According to Klenk and Schuwirth⁵⁵ who based these statements on recent findings of Yokoyama and Suzuki,¹¹⁹ lecithins and cephalins occurring in nature are not chemical individuals but mixtures of various substances. They differ from each other partly in their fatty acids and partly in the glycerin phosphoric acids (α and β forms).

Levene⁶³ has given a tentative formula for sphingomyelin

A plurality of sphingomyelins is assumed.^{14, 115}

According to Thierfelder and Klenk,¹¹⁵ there are four chemically well-defined cerebrosides: cerebron (phrenosin), kersasin, nervon and oxynervon, the structure of which correspond to the general formula

At least four different fatty acids have been isolated, which according to more recent reports (Chibnall, Piper and Williams²⁴) are themselves only mixtures. Still more recently Klenk⁵⁴ has described the isolation of crystallizing neuroaminic acid from the cerebroside fraction of brain lipides. The nitrogen is present as amino acid nitrogen only.

Klenk⁵³ calls attention to the fact that cerebroside and sphingomyelin contain fatty acids with 24 carbon atoms, whereas lecithin and cephalin are characterized by fatty acids with 20 and 22 carbon atoms. He surmises that warm-blooded animals can derive the longer fatty-acid chains from sugar and that the shorter ones result through β -oxidation of the former.

Reaction of Phosphatides with Water

The biological importance of the *lipides* seems to consist in the fact that, unlike the fats, *they are wetted by water*. When the phospholipides and cerebroside in a substance first come into contact with water, part of the water enters the lipide mass, which starts to swell in an irregular manner. These shapes have been called "myeline forms" because of their similarity to medullated nerve fibers. Leathes⁶¹ has explained this behavior by the formation of monomolecular films (see page 1130). When dissolved in water, phosphatides form colloidal solutions, lecithin and cephalin showing a more hydrophilic, and sphingomyelin a more hydrophobic character.

Schmitt and Palmer⁸⁶ reported that this behavior of the phosphatides is reflected in their x-ray diffraction patterns. The highly solvated cephalin and lecithin show spacings that are considerably larger than those of the dry substances, the increment being due to the presence of water between the molecular leaflets at the polar interfaces. In cephalin and lecithin spacings as high as 120 Å have been observed, while the maximal values observed in wet sphingomyelin are about 80 Å. Cerebroside does not emulsify in water, but show strong swelling when heated in the presence of water.

According to Hattori,⁴⁵ the smallest particles of lecithin sols show intensive Brownian movement in the ultramicroscope.

Preparation and Properties of Colloidal Solutions

Colloidal solutions of *lecithin* can be prepared by the method of Porges and Neubauer,⁷⁸ or Keeser,⁵² who add small portions of alcoholic lecithin solutions to water and remove the non-aqueous solvent by boiling. Or lecithin and cephalin can be thoroughly ground and emulsified with distilled water. Even when 1 per cent (Keeser⁵²) lecithin sols are kept in closed "Pyrex" bottles and mould infection is avoided, there is a marked change in appearance within the first days after the preparation of the solution.¹⁰⁰ The sols, which are first translucent and of a reddish-yellow hue, become more opaque, while much of the color fades. During 18 days' observation the electrical conductivity rose from 1.69 to 2.33×10^{-5} mho, the pH dropped from 3.86 to 3.71, while the viscosity showed a drop from 14051/5 to 1380 sec. The interferometric (-refractive) * values remain unchanged. The initial pH values of an emulsified lecithin sol are similar to those reached by the Keeser lecithin sol after 18 days. Fischgold and Chain³² have reported spontaneous changes in lecithin even in the absence of air. Unlike lecithin, cephalin does not show signs of ageing.¹⁰⁴ This checks with findings of Bülow and Page,¹⁴ according to which no hydrolytic cleavage of fatty acids could be observed in cephalin upon prolonged contact with air. The electrical conductivity of a 1 per cent Keeser lecithin sol is 1.69×10^{-5} mho, pH 3.86 $\times 10^{-3}$. Corresponding values for a 1 per cent cephalin sol are 3.10×10^{-4} mho and pH 5.86 respectively. These latter values could be reduced by subsequent dialysis to 9.3×10^{-5} mho and pH 5.33.¹⁰⁴

Further attempts at purification by electrodialysis, which is successful in the case of proteins, have not proved to be equally useful in the case of lecithin and cephalin. Even when an increase of pH was practically avoided (pH 3.73) by the use of a positively charged membrane on the side of the anode, lecithin and cephalin were completely precipitated, during electrodialysis, on the positively charged membrane.

* Measured with an Zeiss interferometer, which is based upon experiments of Rayleigh [*Proc. Roy. Soc. London*, **59**, 203 (1896)].

The redissolved cephalin was more acid than the original solution (pH 4.03 against pH 5.86).¹⁰⁴

Isoelectric Point

The ageing of lecithin shows its influence in the determination of the isoelectric point and, according to Chain and Kemp,¹⁸ may be partly responsible for the large discrepancies in the reported values. Price⁷⁹ reports the isoelectric point of aged lecithin as pH 2.7, and assumes, since this value checks satisfactorily with others reported by Fujii,⁴⁰ Price and Lewis,⁸⁰ and Remesow,⁸² that these authors too have worked with aged material containing adsorbed fatty acids. For freshly prepared lecithin Chain and Kemp,¹⁸ Bull and Frampton¹³ report values of pH 6.7, while the one calculated from the values of the dissociation constants of choline and glycerophosphoric acid and similar phosphoric acid derivatives is pH 7.5. Chain and Kemp¹⁸ determined the isoelectric point of sphingomyelin as approximately pH 7 and found this value very sensitive to impurities.

Dielectric Properties of Phosphatides

Kuhn, Hausser, and Brydowna⁵⁹ have measured the dielectric constant of egg-yolk lecithin (prepared according to Levene and Rolf⁶⁴) in alcohol and in benzene over a temperature range of 20° to 45°. Lecithin was dielectrically active only in alcohol in which it is unimolecular in betaine form. Both cephalin and lecithin are inactive in benzene, in which the latter polymerizes, reaching a molecular weight of about 3000. Studies of Hausser^{46, 47} on sphingomyelin show a molecular resonance effect of the substance. The observed strong, anomalous dispersion is independent of viscosity; therefore the two long, weakly polar groups of the molecule are at rest and the strongly polar group (cholin phosphoric acid) vibrates like a pendulum with a low frequency. The author suggests the importance of these findings for a possible explanation of the behavior of brain and nerve substance to the specific action of short-wave therapy.

Acid and Alkali-binding Capacity

Studies on the ampholytic nature of phospholipids have been reported by Jukes⁶¹ and Fischgold and Chain.³² According to the latter, "the phospholipins, lecithin, lysolecithin, cephalin, sphingomyelin can bind in acid reaction 1 equivalent of H-ions. In alkaline reaction the phospholipins, which possess a primary amino group, give up 1 equivalent of H-ions. The quaternary bases are not capable of this reaction. The phospholipins containing a quaternary NH_4 base can exist only as cations or zwitter-ions, whereas the colamine phospholipins can exist as zwitter-ions, neutral molecules, anions, or cations. The ratio of zwitter-ions to neutral molecules is determined by the two acidity constants." A partial or even total replacement of colamine by serine should not fundamentally alter this concept.

Studies¹⁰⁴ of the reactions of cephalin with acid (HCl) show that a 1 per cent cephalin (human brain) solution becomes more opaque with increasing HCl concentration, until finally precipitation sets in. In 0.02N HCl the solution becomes heterogeneous, though it is still stable. From 0.01N upward centrifuging becomes effective in producing a precipitation of cephalin. Conductivity, pH and viscosity measurements in different HCl-cephalin mixtures give the following results: cephalin neutralizes a certain amount of acid, which increases with increasing HCl concentration to a maximum value; 1 g. of cephalin combines with $8.6 - 8.8 \times 10^{-3}$ ml N HCl. According to what has been said above, one molecule of cephalin in non-aqueous solutions combines with one molecule of acid. As Levene and West⁶⁵ found for brain cephalin having a molecular weight of 823.7, the normality of a 1 per cent solution ought to be 0.0124. The lower values found in these experiments suggest

that not all amino acid groups are freely accessible to the acid. This may be explained by the formation of colloidal aggregates in aqueous solutions.

The behavior of cephalin with HCl is very similar to the behavior observed in proteins with acid,⁷³ except that the computations based on pH and conductivity show that the ionization of the cephalin-HCl complex appears to decrease gradually with increasing HCl concentration.

These results seem to suggest the existence of a compound of cephalin and HCl in solution. However, Thierfelder and Klenk¹¹⁵ reviewing the results of the literature on HCl precipitates of cephalin, came to a different conclusion. In order to elucidate this question, special experiments were undertaken.¹⁰⁴

(1) A solution containing 0.25 per cent cephalin and 0.025*N* HCl shows partial precipitation. A chloride determination in the filtrate after destruction of cephalin with HNO₃, shows that it contains only 90 per cent of the original amount of chlorine. This suggests that about 0.0025*N* HCl has been precipitated with a part of the cephalin.

(2) The conductivity was measured in a 0.25 per cent cephalin sol, in a 0.025*N* HCl solution, and in a solution containing 0.025*N* HCl and 0.25 per cent cephalin. The sum of the conductivities of pure cephalin and pure HCl was larger than the conductivity observed in the solution containing both substances. This difference in conductivities was 10 times greater than the conductivity of the pure cephalin solution. Calculated in terms of HCl normality, the apparent loss in conductivity corresponded to an amount of 0.0025*N*. These results seem to suggest that HCl not only combines with cephalin in solutions, but becomes part of the precipitate when precipitation occurs. By repeated centrifuging and replacement of the aqueous acid layer by pure water, most of the acid can be eliminated. This is due probably to hydrolysis of the lipide-acid compound. The acid cephalin flocculates, when redissolved in water, settles at an acid concentration which primarily did not interfere with stability in centrifugation. But neutralization with alkali restores the original behavior. These findings about the formation of the cephalin-HCl compounds are perhaps not entirely devoid of biological interest; *i.e.*, Peters and Man⁷⁶ claim that part of the chloride of the serum is combined with lipides.

The results of the viscosity determinations made with an Ostwald viscosimeter at a constant temperature of 30° show with increasing concentration of HCl a steady drop in viscosity, which only begins to rise again at a stage preceding precipitation.¹⁰⁹ The initial drop becomes less distinct if the mixtures stand for 24 hours. These observations on the changes of cephalin viscosities upon addition of acids are very similar to those reported by Handovsky and Wagner,⁴³ on lecithin under comparable conditions. But the behavior of cephalin is in this respect markedly different from the behavior observed in proteins; for with the latter increasing HCl concentrations produce at first a rise in viscosity and ionization.

Similar studies were made on lecithin of various origins (egg and human brain).¹⁰⁴ The results of these experiments show that both samples of lecithin bind HCl, but that according to their chemical differences (as indicated by their different pH) the binding capacity reaches its maximal value at a different HCl concentration. The fact that lecithin in aqueous solutions binds HCl is rather unexpected, since, according to Jukes,⁵¹ and Grün and Limpächer,⁴² lecithin is an internally neutralized compound and has no free amino-group. But systematic investigation¹⁰³ of this salt-binding capacity of lecithin sols has given evidence of the sorption power of lecithin. Furthermore, former experiences on globulins⁹² have shown that acid binding can be supplemented by acid sorption.

Attempts were made to study the *alkali-binding capacity of cephalin*. Since the reaction of NaOH with cephalin may lead to some chemical changes in the cephalin, attempts were made to ascertain whether the highest NaOH concentrations used produced a splitting of cephalin.¹⁰⁴ As a breakdown of the cephalin molecule by

alkali ought to liberate fatty acids, conductivity methods could be used in order to trace an increase in conducting material.

Samples containing 1 per cent cephalin and 0.02*N* or 0.05*N* NaOH were exactly neutralized after 24 hours. The conductivities of these solutions were nearly identical with the sum of the conductivities of controls containing either pure cephalin or pure alkali. A slight decrease in the conductivities of the mixtures was explained by the inactivating effect of cephalin on the salt. A splitting of cephalin in the alkali concentrations used in our investigations can therefore be disregarded. The optical changes in cephalin on addition of alkali proved to be reversible on neutralization.

By using a method similar to the one used in the computation of the acid-binding capacity, it can be shown that the NaOH-binding capacity exceeds by far the combination power of cephalin for HCl. Apparently in the presence of excess alkali a maximal value could also be reached.

Viscosity measurements of cephalin at varying NaOH concentrations show a great similarity in behavior to proteins, especially globulins.⁹⁷ Here too, with increasing amounts of NaOH, the viscosity increases and drops again on further addition of alkali. The maximum viscosity is reached at a much lower concentration of alkali than the maximal binding capacity. Yet all these changes occur in the first hours after mixing cephalin and alkali. After several hours of standing, an increase of alkali has uniformly produced a corresponding decrease of viscosity.

The fact that cephalin, though combining with acid like a protein, shows no increase in viscosity like lecithin, may be of some interest to the biologist. The non-swelling of nervous substance in acids (Bauer;¹¹ Spiegel⁹⁰) has been attributed by Hooker and Fischer⁵⁰ to reactions of lecithin prevailing over the reactions of the proteins. This explanation gains new support from the results on cephalin reported here. Thus according to Singer⁸⁹ brain contains more cephalin than lecithin. Recent studies of Spiegel and Spiegel-Adolf⁹¹ have shown that in dead and living brains the polarization indices (a convenient measure of the swelling and the permeability of tissues) show a marked decrease on the addition of alkali, whereas they are unchanged or only minimally lowered in the presence of acids. According to Jukes,⁵¹ lecithin does not bind alkalies.

According to W. and B. Tonnies¹¹⁶ results may be different in separate studies of white and gray matter of the brain. According to those authors, sphingomyelin exceeds in swelling processes all cerebrosides especially in an acid medium. Sphingomyelin is reported to form 8.9 per cent of the white and only 0.1 per cent of the gray matter.

Reaction of Phosphatides with Neutral Salts

Like proteins, phosphatides (unpurified lecithin sols) are precipitated by *neutral salts*; the effectiveness of anions and cations follows roughly the series of Hofmeister and Pauli.¹¹⁵ But there seem to exist two significant exceptions.

(1) Already Koch⁵⁶ and Porges and Neubauer⁷⁸ have reported the great sensitiveness of phosphatide sols to alkaline-earth salts. The small amount of the latter inducing precipitation comes within the range of effectiveness observed in hydrophobic colloids. The high values of the quotient $Q = \frac{CK_{2A}^*}{CK_{1A}}$ derived from this behavior accounts, according to Bungenberg de Jong and Saubert,¹⁵ for the fact that uni-valent salts and bivalent salts have an antagonistic effect in suspended quartz particles coated with lecithin films of different degree of purification. Contrary to Koch,⁵⁶ Bungenberg de Jong and Saubert¹⁵ do not explain the antagonistic effect by a special phosphatide reaction but by interaction of the ions of the medium.

* K_1A indicates a salt of which smaller concentrations are necessary to reverse the charge of a phosphatide than of K_2A . The concentrations producing a reversal of the charge are designated as CK_1A and CK_2A .

(2) *Reactions of phosphatides with neutral salts* were studied with special reference to biological problems. Measurements of viscosity, interferometry and conductivity indicate that, as with proteins, lecithin in colloid solution combines with neutral salt.¹⁰³ But contrary to observations made on proteins, bromides,⁹⁹ in some instances, have twice the effect of chlorides; this becomes particularly marked in the observed decrease in viscosity. These findings, which are perhaps of interest to the pharmacologist, were explained by the action of free bromine. This hypothesis could be substantiated by showing that the specific effect of bromides depends upon the iodine values of the colloid lecithin. Reduction of these values by spontaneous oxidations, irradiation or iodination brings about parallel changes in the specific effects of bromides, which disappear completely in maximal iodination.¹⁰¹ In acidified lecithin and cephalin the Hofmeister series is valid.

Quantitatively, the salt-binding capacity of lecithin sol¹⁰³ depends upon several factors, *e.g.* the time the salt is in contact with the colloid. Special experiments showed that these changes do not depend upon the ageing of the lecithin sol. The amount of salt bound to lecithin sol depends upon the concentration of both salt and lecithin. If the concentration of lecithin sol is kept constant and the amount of KCl varied, then the graphical presentation suggests the existence of a salt-binding maximum in a surplus of salt. The amount of salt bound to lecithin sol depends upon the degree of, dispersity of the latter. Bungenberg de Jong, Verberg and Westerkamp¹⁷ have shown that even small amounts of impurities prevent the formation of a translucent sol. With a different preparation (Merck, 90 per cent pure) the lecithin sols became opaque and milky and the salt-binding capacity of the lecithin sol dropped to about $\frac{1}{10}$ of the original value.

In order to elucidate the type of salt fixation to lecithin sol, two different series of experiments were undertaken.¹⁰³ In aqueous solutions lecithin is negatively charged. Electrophoresis experiments were made using the apparatus of Landsteiner and Pauli.⁶⁰ The KCl solution was varied. Up to 0.1N KCl no change in the anodic movement of the lecithin sol could be detected whereas, according to Koch and co-workers,⁵⁷ the salts with bivalent cations bring about a positive charge on the phosphatides. In systematic investigations on globulins⁹⁷ it could be shown that globulin causes different decreases of conductivity in isonormal solutions of KCl, NaCl and LiCl. This has been explained by the different velocities of the cations and as a proof that part of the cations had been bound to the globulin. Similar experiments made with lecithin sol gave analogous results.

The results of both the electrophoresis and the conductivity measurements seem to indicate that both salt ions are fixed by the lecithin, and that the new compound shows little if any ionization. Under this assumption 1 per cent lecithin allowed to stand for 24 hours in contact with 0.05N KCl binds approximately 18 per cent of the salt.

In another series of experiments the influence of some narcotics on the salt-binding capacity of lecithin was investigated.¹⁰³ Although the presence of ethyl alcohol, ether, chloroform, and chloral hydrate seems to decrease the salt-binding capacity of lecithin, quantitative measurements were attempted only in experiments with homologous alcohols, as these have been studied especially to correlate their chemical and biological behavior.⁴⁸ The results show that with increasing length of chain the effect of alcohols in decreasing the salt-binding capacity of lecithin becomes more marked. In the presence of amyl alcohol the salt-binding capacity practically disappears. At the same time the opacity of the lecithin sol increases, as well as its sensitiveness to salt precipitation. Similar behavior was observed by Freundlich and Rona³⁸ when colloidal ferric hydroxide was treated with narcotics.

Effects of different dielectric constants and changes in the sorption capacity of colloid lecithin brought about by various alcohols have been considered as a possible explanation. Koch and McLean⁵⁸ found no evidence that anesthetics or hypnotics

produce changes in the state of aggregation of lecithin or cephalin. Nevertheless, the most probable explanation of the reported changes of the salt-binding capacity of lecithin in the presence of homologous alcohols seems to be an assumed change in the degree of dispersion of the lecithin sol. The relation between salt-binding capacity and degree of dispersion has been mentioned above. If we may assume that egg lecithin behaves physicochemically like human lecithin, then the diminished ability of the lipides in the cellular surface films to fix salt ions should diminish the reactivity of the cell to stimuli. Changes in ion concentrations must reach a higher threshold in order to act upon the lipides of the cell surface or its interior. In this connection it seems of interest that there is a certain parallel between the narcotic effect of homologous alcohols and their power to lower the salt-binding capacity of lecithin.

Reaction of Lipides with Colloids and Bi-colloids

Since lecithin and cephalin in aqueous solutions are colloids, their *reactions with other colloids and especially bio-colloids* are of particular interest. Both lecithin and cephalin are able to protect colloidal gold against the flocculating effects of neutral salts.¹⁰² Amounts of a 1 per cent cephalin sol greater than 0.1 cc protected 1 cc of the red gold sol when 0.2 cc of normal potassium chloride was added; 0.5 cc of the cephalin failed to protect completely, since the red gold changed to red-violet in color. Smaller quantities showed still less protective action.

Using similar quantities of gold sol and normal potassium chloride, human lecithin showed protective action in quantities of 0.3 cc and above of a 1 per cent lecithin sol; some protective action in quantities of 0.2 cc; little or none in smaller amounts. These experiments demonstrated that cephalin did not precipitate the colloidal gold sol, that presence of cephalin in appreciable concentration protected the colloidal gold against precipitation by potassium chloride, and that the protective action of cephalin toward colloidal gold is greater than is the protective action of human lecithin from the same brain tissue. The protective power of human lecithin is greater than that of egg lecithin (Merck). Both lecithin sols were prepared by the method of Keeser.⁵² In its behavior toward colloidal gold, cephalin shows, therefore, a closer resemblance to gelatin than to the proteins of the blood and of the egg white, which precipitate gold, unless in the presence of electrolytes. Use has been already made of the protective power of phosphatides for industrial purposes. Eichberg²⁸ reports soybean lecithin as an effective stabilizer for leaded gasoline, preventing cloud formation, color change and aluminum corrosion (1—10 pounds of lecithin stabilizing 42,000 gallons of gasoline). The use of lecithin in chocolate confectionery is based, according to Erb,²⁹ upon moisture absorption by the phosphatides. The addition of 0.2 per cent lecithin will protect against increases in moisture content up to 1.5 per cent. Lecithin has also been used in the homogenization of milk,⁷¹ and soybean lecithin may be used as a partial substitute for egg yolk in ice-cream and as a stabilizer of vitamin A in foods. (Stanley¹¹²)

Because of the close connections between *lipides and proteins* in the human body, reactions between these two substances have been studied extensively. Porges and Neubauer,⁷⁸ and Arnd and Hafner⁶ assumed the formation of lecithin-protein compounds; Handovsky and Wagner⁴³ report only negative results. In order to explain this discrepancy special investigations were started.¹⁰⁰

The reaction between *lecithin and serum proteins* used by the former investigators largely depends upon the pH of the solution, the presence of neutral salts, and the age of the lecithin sol. The first point has been extensively investigated by Rona and Deutsch,⁸³ but underestimation of the important role of salt concentration in the relation between lecithin sol and proteins seems to be the reason for contradictory opinions in this matter.

Electrolyte-free solutions of serum-albumin and pseudoglobulin flocculate lecithin sol made from egg or brain lecithin. Fresh samples of 1 per cent lecithin sol are

flocculated to an increasing extent by serum-albumin from 0.4 per cent upward, whereas pseudoglobulin became effective at a concentration of 0.2 per cent. An aged lecithin sol is about 10 times more sensitive to serum-albumin and about 50 times more sensitive to pseudoglobulin flocculation than a fresh one.

According to Freundlich,³⁷ the ageing of lecithin sol consists of changes by which it partially loses its hydrophilic properties and grows more hydrophobic. In good accord with this, the amounts of protein necessary for the flocculation of aged lecithin sol are within the range of the corresponding values for gold sol.⁹⁵ But it seems obvious that the changes reported in the isoelectric point of lecithin upon ageing are the cause of the increased sensitiveness of aged lecithin toward serum proteins. As with most negative sols, the flocculation of lecithin by protein is inhibited by the presence of neutral salts. Since contradictory findings⁶ have been described as to the formation of protein-lipide compounds, systematic studies in this direction were begun.¹⁰⁰

The findings suggest the following interpretation. As long as the salt concentration is sufficient to avoid the faintest signs of flocculation, no changes in the refractive indices are observed. Different salts seem to behave in the same way. If the salt concentration is lowered to a point at which the solution becomes unstable, then the interferometric value of the solution is lower than the sum of the corresponding values for the separate components. The results are the same whether the instability is due to an initial low salt concentration, or whether, through the ageing of the colloid, the salt concentration becomes insufficient. These findings explain the observations of Handovsky and Wagner⁴³ as well as those of Arnd and Hafner,⁶ though they do not necessarily confirm the conclusions of the latter. The decrease in refraction must be explained primarily by a decrease of soluble material. The differences in the flocculating effects of serum-albumin and pseudoglobulin on lecithin sol persist in the presence of neutral salts. Larger quantities of the latter are necessary to prevent flocculation by pseudoglobulin than by serum-albumin. It can be shown that certain serum-albumin-neutral salt combinations can protect lecithin sol against subsequently added pseudoglobulin, although the salt present is not alone able to prevent the flocculating effect of the latter. Such experiments are possible in cases in which there is a gap between the salt concentration capable of inhibiting the flocculating effect of serum-albumin and the salt concentration having the same influence on pseudoglobulin. For this purpose, only lecithin sol of a certain age can be used. In freshly prepared samples, the differences are too slight; in very old sols, the protective power of salts, even against albumin, sometimes vanishes. For these experiments, according to Keeser, one could use only lecithin sols 14-21 days old, fresh emulsions of lecithin in distilled water, or lecithin sols derived from an older, perhaps oxidized sample of lecithin.

These results seem to show that under certain conditions flocculating concentrations of pseudoglobulin fail to produce this effect in the presence of serum-albumin and neutral salt. Though the neutral salt at the same concentration is, in itself, not sufficient to prevent the flocculating effect of pseudoglobulin, its presence is necessary to give the serum-albumin protective power. A non-flocculating concentration of the latter in an electrolyte-free medium is unable to inhibit the precipitation of lecithin sol by pseudoglobulin. The negative result of interferometric investigation made in order to trace some reaction between electrolyte-free serum-albumin and pseudoglobulin is in accordance with these findings. For this reason, the above-mentioned influence of the neutral salt-serum-albumin compound on pseudoglobulin cannot be directly compared with observations made by Pauli and Singer,⁷⁵ who found that albumin prevented, to some extent, the flocculation of certain colloid dyes by serum-albumin in the absence of salt.

Next to the salt concentration, the protective power of lecithin depends upon the ratio of serum-albumin to pseudoglobulin. If the latter falls below $\frac{2}{3}$ - $\frac{1}{2}$, precipitation

begins. It seems, therefore, that the behavior of the total protein mixture toward the lecithin sol depends on the relation of its components. The similarity of this behavior to that of serum under various pathological conditions is somewhat striking. There, too, the so-called albumin/globulin quotient (Hoffmann⁴⁹) seems to determine, in many cases, the properties of the serum and other biological fluids. The reactions of spinal fluid toward gold sol in particular seem to depend largely on this property according to Schmitt.⁸⁷ An increase of globulin has been described in nearly all luetic changes. The above-mentioned results may be of some value for a further understanding of luetic reactions using flocculation methods (*e.g.* the Meinicke and Lange tests for syphilis).

There exists a marked, although possibly only quantitative, difference in the behavior of cephalin and lecithin (both derived from the same human brains) toward serum proteins.

Neither serum albumin in concentrations up to 1 per cent nor pseudoglobulin in concentrations up to 2.5 per cent cause any precipitation in fresh samples of cephalin.¹⁰² In aged samples of cephalin no apparent change was called forth by serum albumin, although 1-2.5 per cent pseudoglobulin caused an increasing cloudiness. Even an interferometer did not show a change in the degree of dispersion of a cephalin sol upon the addition of serum-albumin, such as has been found in lecithin-protein mixtures when flocculation had been prevented by a low amount of salt. A 0.25 per cent cephalin solution gave an interferometer reading of 75 units, a 0.25 per cent serum-albumin sol a reading of 112 units and a sol containing 0.25 per cent cephalin and 0.25 per cent serum-albumin a reading of 189 interferometer units, this latter being within experimental error of the calculated 187 which should have been obtained had the values been additive.

The above-mentioned differences in the behavior of cephalin and lecithin can be used as tests for the protective power of cephalin on lecithin against the precipitating effect of protein. Lecithin of human brain was used in these experiments. In spite of the fact that cephalin sols mixed with lecithin sols show added values in the interferometer and therefore do not indicate a change of dispersion,* nevertheless the influence of cephalin on lecithin becomes very marked when protein is present.

Cephalin apparently protects against the precipitating effect both of serum-albumin and pseudoglobulin. In a 0.6 per cent serum-albumin sol containing 0.5 per cent of lecithin there was an immediate precipitation when 0.025 per cent or less of cephalin was present. If, however, the cephalin concentration equaled 0.05 per cent or more, no precipitation of the albumin-lecithin system took place. The importance of using cephalin-free samples of lecithin for physical-chemical tests is evident. On one hand these findings may explain the discrepancies in the literature about the flocculating effect of proteins on lecithin sols; on the other hand, they show that there exists a mechanism besides the action of neutral salts that is able to prevent flocculation of lecithin by proteins. These phenomena also may be interpreted as instances of cumulative protection as described by Alexander.⁴

In connection with the problem of blood coagulation, Chargaff and co-workers¹⁹ have studied the reactions of phosphatides particularly with basic proteins. They report noteworthy differences in the behavior of cephalin and lecithin. Cephalin forms salt-like compounds with salmine, a protamine, over a pH range of 2-11, lecithin only at pH 10-11. Sphingomyelin is not precipitated by addition of salmine. Cephalin forms precipitates with thymus proteins at pH 2-7, lecithin only at pH 7-8. It is pointed out that the ability of the basic proteins to precipitate cephalin at a physiological pH parallels their inhibitory effect on blood coagulation in a marked way. Cephalin forms a compound with egg-albumin at pH 2-4; no analogous phenomenon is observed in lecithin. Similar behavior has been noted in histon, which

* According to Bull,¹² the wide difference in isoelectric points of the two lipides is suggestive of coacervate formation over a considerable range of pH.

apparently reacts with cephalin only at a pH less than 4.0. Only cephalin is able to disrupt the heme-globin linkage in oxy- and CO-hemoglobin by forming cephalin-globin compounds. These differences are supposed to indicate different biological rôles of cephalin and lecithin in the organism.²⁰ Chargaff¹⁹ gives an extensive description of the compound formed by cephalin and salmine. The dried precipitates are characterized by a P:N ratio of 1:4 or 1:5; they swell in contact with water to a rubber-like consistency; they can be recrystallized from ethyl alcohol, etc. A further elucidation of the structure of such compounds is given by Schmitt and Palmer⁸⁶ in collaboration with Chargaff; they studied x-ray diffraction patterns of precipitates of cephalin with basic proteins. Depending on the protein used an increase of 10-15 Å above the spacing of cephalin was found. Therefore, the existence of only one more layer of protein can be assumed between each double layer of cephalin.

Schmitt and Palmer⁸⁶ assume that "the protein molecules are spread out flat at the polar interfaces of the cephalin layers and the binding of the negative groups of the cephalin by the positive groups of the basic proteins on both sides of the protein monolayers causes the collapse of the highly solvated cephalin system and the expulsion of water." Approximately 70-80 Å of water can be expelled in this way, indicating the extensive changes brought forth in lipid systems by the introduction of basic proteins. Reactions of lecithin with casein have been studied by Parsons,⁷² who devised a colorimetric method to determine the amounts of lipid and protein entering into reaction. He explains the latter as a precipitation of colloids with opposite charge, the amount of which depends on the pH of the medium.

Fujii⁴⁰ reports a dehydrating effect of egg albumin upon lecithin by which the solubility of the latter in ether is increased. Bamberger⁹ studied the influence of lecithin upon gelatin gels. He found an increase of the swelling capacity of 12-15 per cent independently of the pH, while the bound water, measured by the method of Rübner, is diminished. The behavior of cholesterol sols is antagonistic to lecithin, as it decreases the swelling capacity by 8-10 per cent but is apparently without influence on the amount of bound water.

It is impossible to give here even a short review of all the papers dealing with the relation of protein and lipid in serum (see globulins).⁹⁷ But it seems worthwhile to note the fact that, according to Went and Kuthy,¹¹⁸ some of the changes brought forth in serum proteins by lipid extraction may be caused by partial denaturation of proteins.

There exist some references to a direct *influence of lipides upon heat-denaturation of proteins*. Bancroft and Rutzler¹⁰ report that heat-coagulation of egg-albumin can be prevented through previous extraction with peroxide-free ether, which removes a lecithin-like substance. Pauli and Omar⁷⁴ have been able to show that through simultaneous removal of CO₂ the pH is shifted from pH 6.28 to pH 8.44, at which no heat coagulation occurs. Nevertheless, experiments with dialyzed cephalin ($K = 9.3 \times 10^{-5}$ mho, pH = 5.33 in a 1 per cent solution) showed that, like gelatin, it was able to prevent heat coagulation in serum-albumin of twice its own concentration, and failed to do so when the relation of cephalin to serum-albumin was increased to 1:3. In all these experiments the lipid protein mixtures and the controls were heated for fifteen minutes in a boiling-water bath.¹⁰²

Baker, Harrison, Miller and Wexler⁸ report an inhibition by phospholipides of the action of synthetic detergents on bacteria. They discuss the possibility that the phospholipides act by preventing a denaturation of the proteins of the bacterial membranes through the detergents.

Finally the effect of cephalin on *cholesterol sol* was studied. In order to have comparable data for human lecithin all experiments were made with this substance. The sol of cholesterol (Merck) was made according to the method of Keeser. After filtration the milky solution was fairly stable.¹⁰²

In preliminary tests the reactions of the cholesterol sol toward neutral salts, serum-albumin and pseudoglobulin were investigated. The observations were in harmony with results of former investigators. In series of experiments it was shown that cephalin as well as lecithin is able to protect cholesterol sol against flocculation by salts or proteins. In a system containing 0.5 per cent cholesterol and 0.1 cc of a normal potassium chloride, cephalin in 0.0016 per cent nearly inhibited the flocculation of the cholesterol. When the cephalin concentration was 0.0024 per cent or greater, the flocculation was completely inhibited. Flocculation was likewise inhibited in a similar system when lecithin in concentration of 0.2 per cent or more was used instead of cephalin.

In a system containing 0.5 per cent of cholesterol and 0.05 per cent serum-albumin, cephalin in concentration of 0.01 per cent or more inhibited flocculation, whereas definite flocculation took place in a similar system when lecithin was present to the extent of 0.05 per cent; but no flocculation of the cholesterol-protein system took place when the lecithin concentration was raised to 0.1 per cent.

These findings may have to be considered in all cases in which the role of protective colloids has been thought important for the stability of cholesterol, *e.g.*, in the formation of concretions under pathological conditions.⁹⁸

Chargaff and Ziff¹⁹ have given evidence of salt formation between cephalin and the basic dyes methylene blue and thionine. No similar behavior was observed in lecithin. *Reactions of lipides with dyes* are of interest for the evaluation of histochemical reactions. According to Shapiro,⁸⁸ only cerebrosides but not phosphatides respond to the usual dyeing method, since the results became uniformly negative upon extraction with acetone. The author explains this behavior by the fact that phosphatides are bound to proteins. Extracted lipides, according to Diamare,²⁶ are not changed in their birefringence by treatment with "nilblau" or Sudan III after the usual fixation methods.

No theory has as yet been advanced as to the nature of the special structure of the cephalin molecule to which protective power of the lipide is due. Some evidence for such formulation might be obtained, however, by the results of the following experiments. It was ascertained that the protective power of cephalin on colloidal gold is practically unchanged after the solution has been boiled. This is in agreement with the results reported on the protective power of cephalin against the heat coagulation of protein, and proves that the protective power of cephalin is heat-stable within a certain pH range. On the contrary, the protective power of cephalin on cholesterol is practically completely destroyed by intensive irradiation with ultraviolet light (quartz mercury lamp, Hanovia, 220 V.d.c., four hours at 20 cm distance, 0.25 per cent cephalin sol). Thus, for example, a 0.5 per cent cholesterol sol containing 0.1 cc of normal potassium chloride was not protected, even when a quantity of irradiated cephalin as great as 0.8 per cent was added to the system.¹⁰²

The *irradiated* cephalin sol does not show gold sol flocculation as observed in proteins under similar conditions, nor hemolysis of erythrocytes as has been described by Fabre and Simonnet³⁰ in irradiated lecithin, through the formation of lysolecithin-like substances. At all events, according to Magistris,⁶⁹ a sample of lecithin free from lysolecithin is not hemolytic. As with proteins, heat and short-wave light have a different effect on cephalin. An analysis of the effects of irradiation may, therefore, be helpful for the understanding of the protective power of cephalin.

Monomolecular Films of Phosphatides

Leathes⁶¹ has observed the spreading of lecithin as *monomolecular films* on water, and explains the film formation by the fact that lecithin contains two polar groups. The hydrophobic paraffin chains try to escape from the surface of the water, while the hydrophilic glycerophosphocholic groups are anchored in the surface. The

film is formed by the cohesive powers between the hydrophobic groups standing nearly vertical to the surface of the water. By measuring, according to the method of Adam,¹ the surface of a monomolecular film taken up by a certain quantity of a certain substance, it is possible to compute the space occupied by one molecule of the substance. In this manner Leathes was able to show that the paraffin chains in lecithin are less closely packed than in fatty acids. This seems to facilitate the exchange of water and other substances and to indicate the biological importance of lecithin films. Alexander and Theorell² have included cephalin in similar studies and found (Alexander, Theorell and Aborg³) that cephalin films are stabilized by calcium ions.

Phosphatides in Artificial Membranes

The importance of lipides for polarization effects in biological membranes has been stressed by various authors.⁶⁷ Experiments on artificial membranes have been made in order to elucidate this phenomenon.¹⁰⁵ The artificial membranes consist of a sintered glass plate on which various colloids can be adsorbed. The polarization is determined by the polarization index, computed from conductivity data obtained at various frequencies and by measurements of potential differences.¹¹¹ It could be shown that the existence of polarization depends upon the presence of lipides (lecithin), although the synergistic action of another colloid (protein or starch) is necessary. The role of the latter substances seems to be more of a mechanical nature, *e.g.*, that of decreasing the size of the pores in the sintered glass plates.¹⁰⁵

Such artificial composite membranes containing lecithin show a number of reactions observed in biological membranes only, *e.g.*, the specific effects of bromides, increase of polarization in the presence of magnesium salts, increased polarizability upon substitution of ethyl alcohol (used as solvent for lecithin) by a higher homologous alcohol of greater narcotic effects, etc.

Molecular Orientation of Phosphatides

Although cephalin and lecithin look amorphous in solid form, their particles acquire a certain degree of orientation upon swelling.⁶² Under the influence of the water the particles become moveable against each other and can be oriented by surface tensions.⁵

Studies in birefringence of lecithin have been made by H. Ambronn.⁵ According to Göthlin⁴¹ the oleic acid radical of the latter is responsible for this behavior.

X-ray diffraction patterns of lecithin, cephalin, and sphingomyelin from mammalian central nervous system have been reported by Schmitt, Bear and Clark⁸⁵ and Schmitt and Palmer.⁸⁶ According to these authors, all three phosphatides show diffraction line or lines corresponding to spacings between 4.22-4.65 Å. Lecithin and cephalin show also spacings of about 46 Å; sphingomyelin has a diffraction line corresponding to spacings between 63-67 Å. Schmitt and Palmer⁸⁶ take about 46 Å as the characteristic spacing of lecithin and cephalin.

Our own observations 107-109 have concentrated upon x-ray diffraction patterns of various lecithins and cephalins from the human nervous system, from soybean phosphatides, and egg-lecithin upon the influence of different steps in purification and upon experimental factors able to influence the x-ray diffraction patterns of these substances. Comparative studies of x-ray diffraction patterns of lipides show similarities and differences. All lipides under investigation show a diffraction ring or rings corresponding to spacings of approximately 4.5-4.8 Å. This checks with the above-mentioned findings of Schmitt, Bear and Clark,⁸⁵ although our technique was not chosen to give complete x-ray diffraction patterns. Three of our lipides show also faint rings corresponding to spacings of 2.90-3.1 Å.

Differences in the diffraction patterns seem to exist between lipides of different origin and within lipide individuals of the same group. In egg lecithin and in all

soybean phosphatides the main ring (4.35-4.51 Å) is diffuse, approximately 2 mm wide. In cephalin and lecithin from human brain there are several fairly sharp rings instead of a diffuse one, which correspond roughly in spacing to the latter.

Within the various groups no differences can be found between lecithin and cephalin from soybean in respect to the main spacing. But in the group of human brain lipides such differences are manifest. Purified human lecithin contains two more rings than the corresponding fraction of cephalin. Diffraction rings corresponding to spacings between 2.9-3.1 Å are observed in two types of egg lecithin, in crude, but not in purified lecithin from human brain, and in one cephalin from soybean. This seems to suggest varying effectiveness in fractionation.

Both the similarities and the differences between the members of the human brain and the soybean group seem significant. Already Schmitt and co-workers^{85, 86} had reported that they had noticed "that dry samples of lecithin and cephalin give frequently two long spacings rather than one." They explain these lines either by the presence of mixtures of carbon chains of varying length and possibly varying angles of tilt (Malkin⁷⁰) or by the presence of groups which are not clearly defined.

Our own investigations¹⁰⁹ have shown that the spacings of 4.17 and 4.6 Å observed in dried lecithin also occur in oleic acid upon freezing. As unsaturated acids are essential constituents of both lecithin and cephalin, this fact suggests that the above spacings too are characteristic of the phosphatides and worthy of further study. Attempts were therefore made to produce changes in the lipides which might influence their x-ray diffraction patterns. A few preliminary experiments were made with the crude sample of human lecithin. Drying over P_2O_5 to weight constancy does not, apparently, change the x-ray diffraction pattern in human lecithin in which sharp lines already exist in the spacings between 4.5-4.8 Å. But a sharpening of the diffuse band upon drying could be observed in soybean lecithin. Heating for two hours at 105° changes the inner of the three sharp rings of human lecithin. Further purification of the crude lecithin sample brings out a fourth ring in the pattern.

Since in a number of fluid fatty acids, freezing produces a separation of the diffuse diffraction band into several sharp lines,¹¹⁰ similar experiments were tried on soybean lecithins of viscous consistency.¹⁰⁹ A separation into at least four separate lines (3.67, 3.86, 4.17, 4.6 Å) was achieved. But this method failed for obvious reasons in the case of solid cephalins. Therefore another procedure, known to produce dehydration and increase of crystallinity at least in proteins, has been tried. Previous experiences in proteins have shown that sharpening of the so-called backbone reflection is brought forth by different kinds of denaturation. A sample of euglobulin, which had lost its salt solubility by extensive purification, showed sharpening and splitting of the backbone reflection. The latter phenomenon has been described in heat denaturation of proteins by Astbury and Lomax⁷ and has been confirmed by Spiegel-Adolf and Henny,¹⁰⁰ who have been able to show parallelism between x-ray diffraction pattern changes and reversibility of protein denaturation.^{94, 96} Experiments were therefore started to study possible heat changes in lipides and to correlate them to the x-ray diffraction patterns of these substances. For obvious reasons soybean lipides were chosen for these experiments, since the x-ray diffraction patterns of these substances are originally diffuse rings. Nevertheless, we have duplicated the experiments to be reported here with lipides from human brain.

A technique of heat denaturation in lipides^{107, 108} was developed. Since maximal heat precipitation occurs in proteins at isoelectric reaction and in the presence of neutral salts, cephalin was investigated under similar conditions. The aqueous solutions of cephalin from soybean and from human brain have a pH of 6.82-6.95 and 5.86 respectively. According to Thierfelder and Klenk,¹¹⁵ the isoelectric point of cephalin is pH 2.7. This corresponds rather closely to the reaction of 1 per cent cephalin from human brain containing 0.01N HCl ($cH=2.28 \times 10^{-3}$, $pH=2.64$).

Such a solution does not show any changes upon heating, nor does a 1 per cent cephalin solution containing 0.15*N* KCl. A 1 per cent cephalin solution containing both 0.01*N* HCl and 0.15*N* KCl is stable at room temperature for at least 48 hours, but shows very marked precipitation upon boiling in a water bath. No precipitation occurs when the neutral salt is added after boiling and cooling of the acidified cephalin solution. The importance of the sequence of salt addition and heating for the occurrence of coagulation in proteins has already been stressed.⁹⁴ Lecithin from soybean shows upon heating a behavior similar to cephalin. These observations on cephalin and lecithin apparently show the existence of heat precipitation in both cephalin and lecithin under specific conditions. Since it has been found that this can be induced in protein material already heat-denatured,⁹⁸ heat precipitation alone cannot be accepted as a sufficient proof for the existence of heat denaturation. It seemed, therefore, of sufficient interest to examine the x-ray diffraction of lipides subjected to heat precipitation.^{107, 108} To obtain x-ray diffraction patterns of the heat-precipitated lipides it is necessary to remove the salt and acid added to induce heat precipitation. When practically all the electrolytes are removed, heat-precipitated cephalin remains for the most part insoluble in the aqueous medium, while the heat-precipitated lecithin spontaneously goes into colloidal solution. Both preparations were dried in vacuum desiccators over P₂O₅. In order to get comparable materials, lecithin and cephalin that had been boiled in the absence of electrolytes were treated in the same way. The x-ray diffraction patterns indicate differences in the behavior of heat-precipitated cephalin and lecithin. Heat-precipitated cephalin shows a sharpening of the otherwise diffuse ring which is similar to the so-called "backbone sharpening" in proteins.⁷ It would, therefore, seem probable that cephalin is not only precipitated but also denatured (dehydrated) by heat. Cephalin that was simply boiled in the electrolyte-free solution showed the same diffuse ring as the genuine sample, except that the faint ring corresponding to a spacing of 2.90 Å became still fainter in the heat-precipitated sample. No changes could be observed in the diffraction pattern of heat-precipitated lecithin; it is identical with the patterns of boiled and ordinary lecithin.

Since heat-denatured serum-albumin regains its water-solubility and original x-ray diffraction pattern after treatment with diluted alkali,^{94, 108} similar experiments were started on heat-precipitated cephalin. The precipitate dissolved very easily and after subsequent neutralization, dialysis and desiccation, the x-ray diffraction pattern once more showed a diffuse ring, similar to the pattern of the original preparation. Even the faint ring at 2.90 Å again became more visible. Heat denaturation of proteins had previously been interpreted as a condensation of the terminal positive and negative groups under ring formation.^{94, 96} The isoelectric reaction conditions are optimal for an equal number of positive and negative terminal groups. A decrease of hydration induced by the addition of neutral salts ought to facilitate reactions between different protein molecules. It is interesting that similar conditions are necessary for heat precipitation of monophosphatides. Heat denaturation is observed only in cephalin, which like protein is an ampholyte, *i.e.*, it combines with both acid and alkali. It is absent in lecithin, which according to Jukes,⁵¹ has no ampholytic properties in aqueous solution. Heat denaturation seems to have an effect, at least on cephalin, that makes its x-ray diffraction pattern approach that of brain cephalin. It would, therefore, seem correct to explain the differences seen in the x-ray diffraction patterns of the soybean and human brain lipide group as due to the more drastic treatment to which the latter lipides have been subjected. The differences reported in the pattern of crude and pure lecithin from human brain seem to point in the same direction. Hansteen-Cranner⁴⁴ claims that most lipides become denatured upon extraction. Our findings confirm the existence of lipide denaturation, which has been already conjectured on the basis of changed protective action in irradiated cephalin. Conversely, the differences in denaturation of lipides, as assumed from differences of their x-ray diffraction patterns, may be mostly of a quantitative nature.

Physicochemistry of Cerebrosides

There exist only very few *physicochemical* and *colloid-chemical* investigations of *cerebrosides*. Both the monograph of Thierfelder and Klenk¹¹⁵ and the review of Klenk and Schuwirth⁵⁵ contain a chapter devoted to the physical chemistry of phosphatides; but an analogous presentation of cerebrosides is lacking. Nevertheless, a few items pertaining to physicochemical aspects of cerebrosides could be collected, besides the determinations of optical rotation and melting point used for the characterization of the single individuals.

Occurrence of myelin forms and liquid crystals (Rinne⁸¹) has been reported before. The cerebrosides crystallize well. It seems worth mentioning that there exist characteristic differences in the birefringence of the crystals of individual cerebrosides. Rosenheim⁸⁴ has based on this behavior a test of purity of either cerebrin (phrenosin) or kersin. X-ray diffraction studies on dry phrenosin and kersin have been reported by Schmitt and Palmer.⁸⁶ According to these, kersin and phrenosin show, besides diffraction lines corresponding roughly to the ones of lecithin and cephalin at 4.2 Å, others corresponding to spacings at 67 and 48 Å respectively. The x-ray diffraction pattern of kersin is very similar to the one of sphingomyelin.

Chibnall, Piper and Williams²⁴ have used x-ray diffraction studies to ascertain the nature of fatty acids in phrenosin and kersin. They found that three phrenosins exist in brain and at least three kersins which are compounds of different fatty acids. Similar investigations have been made by Crowfoot.²⁵

Spectrographical studies of kersin have been reported by Dworacek and Pesta.²⁷ According to them, the graphical presentation of the log of the extinction coefficients of kersin shows a maximum between 2675-2700 Å and a minimum between 2475-2525 Å. The authors have made use of their findings for tracing amounts of kersin in the serum of guinea pigs after intraperitoneal injections with this cerebroside.

Teunissen¹¹³ has used colloid-chemical methods to determine the purity of cerebroside and sphingomyelin from beef brain. In an earlier paper Bungenberg de Jong and Teunissen¹⁰ established by electrophoretic measurements the sequence in which salts with positive ions up to a valency of six reverse the electric charge of negative colloids. This sequence of salts is characteristic for certain ionogenetic groups in colloids (phosphate, carboxyl, and sulfate groups). The same authors also described a way to determine the number of ionogenetic groups (charge density) for 1 g of dry colloid by the method of reciprocal hexol numbers (hexol nitrate is a complex 6-valent cobalt compound). Teunissen found that cerebrosides, which according to their structure are devoid of ionogenetic groups, nevertheless show not an infinite hexol number but a definite one, indicating the presence of a small amount of ionogenetic groups (61,000 g corresponding to 1 equivalent). Upon spontaneous oxidation there was a further decrease of the reciprocal hexol number, which could be brought back to the original value by recrystallization. The sequence of the salts reversing the electric charges clearly indicated that the ionogenetic groups in question were carboxyl groups.

Sphingomyelin, which because of its ampholytic character should have an infinite hexol number, gives a value of 76,000, indicating the presence of a small non-compensated negative charge. By comparison with the sequence of salts reversing the charge in egg lecithin the negative group could be identified as the phosphate group, due to a small cleavage in the positive cholin group.

Attempts to determine new physicochemical characteristics were further reported by Hausser,^{46, 47} who also studied the dielectric constant of phrenosin. Turner and Watson¹¹⁷ have studied surface films of phrenosin and kersin besides sphingomyelin. For each substance the area occupied by the molecule in a closely packed surface film can be compressed to about 42 sq Å. These figures are in good agreement with the supposition that the limiting value is the area occupied by the paraffin chains, set side by side vertical to the water.

According to Lieb⁶⁶ and co-workers the carbohydrate group in cerebrosides is responsible for their "chromotropic reaction" (i.e., changing the color of an aqueous thionine solution).

Physicochemical Mechanisms in Neuropsychiatric Disorders

E. A. SPIEGEL, M.D.
Professor of Experimental Neurology

and

M. SPIEGEL-ADOLF, M.D.
Professor of Colloid Chemistry

Temple University • School of Medicine, Philadelphia, Pa.

Nervous and mental disorders may more or less easily be understood as due to deviations from normal functioning of the central nervous system, involving morphologic changes which are macro- or microscopically demonstrable in this organ. In a group of pathologic conditions, however, our present morphologic methods are unable to demonstrate structural alterations. In some of these functional conditions it may be sufficient to assume that they are purely 'psychogenic,' as for instance in hysterical manifestations which may be influenced by suggestion. In the majority of cases, however, the inability of morphologic methods to discover an "organic" basis of a neuropsychiatric disorder should not be accepted as a sufficient proof of psychogenic origin and of the absence of a structural or organic cause of the dis-

turbance. This leads one to the question whether changes in the physicochemical and particularly in the colloid-chemical state of parts of the central nervous system may be demonstrable in some neuropsychiatric disorders and may play a rôle in their genesis.

It is attempted here to discuss (1) what various types of physicochemical and especially colloid-chemical changes may be observed in and correlated to neuropsychiatric disorders; (2) to outline the conditions and factors causing or influencing such changes; and finally (3) to review the methods of investigation which may be of use in such studies.

Types of Changes Observed

Changes of the Cell Colloids. *State of hydration.* Brain swelling¹⁴⁶ may be found in various pathologic conditions: after brain trauma, in acute intoxications, (*e.g.*, uremia) and infections (*e.g.*, diphtheria), inflammatory and vascular processes, brain tumor (particularly gliomas^{48, 85, 149, 155, 175}), delirium tremens, status epilepticus, catatonic states in schizophrenics. In a number of cases the underlying pathologic process remains undetermined. The importance of brain swelling lies first in the production of increased intracranial pressure due to the increased volume of the brain, particularly if the swelling affects the whole brain, and secondly in the production of local symptoms if the swelling occurs in certain areas only. The localized form may accompany circumscribed organic processes such as tumors, not only in their vicinity but also in distant parts of the central nervous system, thus complicating the clinical picture and rendering more difficult the local diagnosis. The fluctuating character of the signs and symptoms produced by localized brain swelling and their retrogression on application of dehydrating measures may help to differentiate them from those caused by the primary process.

It is important to distinguish true brain swelling, *i.e.*, increase of volume due to reversible water binding (hydration) of the cellular elements and their processes, from edema, *i.e.*, increase of fluid in the interstitial spaces of the tissue. Macroscopically, one finds in cerebral swelling that the convolutions are flattened and pressed against the skull so that the subarachnoid space is almost completely obliterated and contains scarcely any cerebrospinal fluid. Histologically, glial changes, particularly ameboid cells⁸ were found, but they are not specific.¹⁵⁵ Scheinker¹⁴⁹ describes rarefaction and hydration of the ground substance, hydration with swelling of the myelin sheaths, axis-cylinders and glial cells and mild functional vascular disturbances (stasis and diapedesis); cerebral edema shows increase in the permeability of the vessel walls, distension of the perivascular spaces, transudation of serous fluid into the nerve tissue around the blood vessels with resulting liquefaction of the tissue, distension of the pericellular spaces and areolar and sieve-like appearance of the nerve tissue. Both conditions may frequently be combined in the same brain, and some authors even seem inclined to consider brain swelling as chiefly due to increase of extracellular water (see page 1146). The above-mentioned histological criteria are important, therefore, since they may help one to recognize how far true hydration, apart from edema, may be held responsible for brain swelling.

The swelling chiefly affects the white matter and much less the cortical gray. Due to the increased intracranial pressure the cortical gyri are usually flattened. The differences in the swelling of the gray and white matter is explained by W. Toennis¹⁷⁹ by the fact that the cortex contains only 0.1 per cent sphingomyelin, whereas the white matter contains 8.9 per cent of this substance, which is said to have the highest hydration capacity of all the phosphatides.

Very little is known about the genesis of brain swelling. A common denominator for the great variety of heterogeneous conditions in which brain swelling was found seems the rather acute destruction of nervous tissue within diffuse areas of the central nervous system. Such a view is corroborated by the appearance of the so-called

aneboid glia (Alzheimer), a type of glia cell which shows that noxious agents are present inducing a proliferation of glia cells as well as injuring these proliferating cells. The possible rôle of the destruction of white matter is indicated by the observation that the birefringence of the myelin sheaths decreases as early as 24-48 hours after severance of a myelinated nerve.¹⁵⁸ Since this decrease of the birefringence is reversible, at least in its initial stage, and a similar reversible decrease is observed in hydration of the myelin sheath,¹⁵⁹ it seems not improbable that a swelling of the myelin sheath takes place in the beginning of the Wallerian degeneration. Such a view is supported by the fact that the water content of degenerating nerves^{113, 127} or central nerve tracts⁹⁵ is increased. Similar findings were reported for brain tissue in various pathologic conditions with degeneration of nervous tissue associated with decrease of lipoids such as general paresis,⁹³ dementia praecox,^{96, 142} and pellagra.^{97, 98} The breakdown of lipoids accompanying degeneration of nervous tissue seems to play an important rôle in the genesis of brain swelling. There appear increased amounts of hydrosoluble phosphorus in degenerating nerves¹¹⁴ probably partly because of the disintegration of nucleoproteins and phosphatides that leads to the formation of phosphoric acid; the appearance of this acid is able to increase the state of hydration of proteins (*e.g.* of globulins¹⁷⁰).

Another mechanism is indicated by the finding of Weil¹⁸⁵ that the benzene-soluble lipoids inhibit the swelling of proteins. Thus the diminution of lipoids in degenerative processes may favor the swelling of proteins. A further factor to be considered is the accumulation of cleavage products that may facilitate the swelling. According to Weil,¹⁸⁵ and de Crinis,³² such a rôle may be played by urea, which increases the hydration of gelatin and fibrinogen.^{42, 73} de Crinis, using the xanthidrol method, found increase of urea in the cerebral tissue in brain swelling due to various diseases. However, it is not proved that an increase of the water-binding power of the cell proteins is the decisive factor in the mechanism of brain swelling, since this process chiefly affects the white substance in which, according to Fraenkel & Linnert,⁴⁴ 74.8 per cent of the dry substance is lipoids. Increase of the permeability of the cells and their processes under the influence of toxic or other injurious agents may be an additional factor. It should also be emphasized that osmotic processes, apart from pure hydration, may play an important part in the mechanism of brain swelling. Such osmotic processes may come into action because of the accumulation of cleavage products in the tissue on the one hand, and to the decrease of water-binding substances (*e.g.*, proteins) in the blood plasma on the other.

Changes opposite to those observed in brain swelling, *i.e.*, shrinkage of the protoplasm due to a diminished water-binding capacity (synaeresis), may play an important part in normal and in pathologic or premature senescence of the central nervous system, as well as of the organism in general.^{148a} As pointed out by Braunnuehl,^{17a} such processes may cause, for example, the appearance of the so-called senile plaques or of the changes of the neurofibrils described by Alzheimer.

State of dispersion. Bancroft^{8, 9} and his associates tried to establish a relationship between the state of dispersion of the brain colloids and mental disorders. He assumed that these colloids are slightly "overcoagulated" in the one group (manic-depressive psychoses) and overpeptized (over-dispersed) in the other (schizoid insanity). He supports his theory by experiments attempting to show that coagulating agents produce narcosis, whereas a peptizing agent such as sodium thiocyanate has an antagonistic effect to anesthetics. Henderson and Lucas,⁷⁴ however, failed to find a specific antagonism between sodium thiocyanate and several narcotic agents, and emphatically reject a coagulation theory of narcosis. Similarly Leake¹⁰² was unable to confirm an antagonism between sodium thiocyanate and morphine. Harris and Katz⁷⁰ tested the effects of sodium amytal and sodium rhodanate, these being drugs which Bancroft recommended as coagulating and peptizing agents, respectively. While sodium amytal may have a transient ameliorating action on mental patients,

sodium rhodanate was without noticeable therapeutics effect. Contrasting effects between these two drugs having diagnostic value could not be found.

In view of the difficulty of obtaining direct information about the state of the brain colloids, serological studies are of interest; for they may perhaps shed some light also upon the colloids of the nervous system. Ludlum and Zozaya,¹⁰⁹ studying sera of mental cases, distinguish four groups of chemical patterns: (1) normal distribution of the different protein fractions, found in normal individuals, chronic demented cases, and diseases of purely psychological nature; (2) increase of the euglobulin fraction, found in acute psychoses produced by bacterial invasion and associated with disturbances of water interchange between blood and tissues; (3) increase of pseudoglobulin found in intoxications; and (4) increase in albumin observed in schizoid constitutionally inferior individuals, in whom Krause¹⁰⁰ reported globulin increase. In similar studies Frisch,⁴⁷ and Georgi,^{53a} observed in epileptics, preceding the attack, an increase of serum protein, due to an increase of albumin, "the finely dispersed fraction" while the "coarsely dispersed" fractions showed normal values. In reviewing these studies one has to bear in mind that deviations in the proportions of the various protein fractions of the serum can be found in many conditions without mental or nervous disturbances, *e.g.*, increase of euglobulin in luetics,¹²⁸ increase in pseudoglobulin in experimental active immunization,^{9a} increase in albumin* in experimental exposures to cold⁸⁴ and under the influence of high altitudes.^{45a}

It seems, therefore, that other factors still unknown (perhaps in addition to the above-mentioned changes in the protein fractions) must be held responsible for the genesis of mental disturbances.

In a study of the precipitation of the plasma colloids by NaCl, Georgi found an abnormal lability of the plasma colloids (without change of the sedimentation rate of the red blood corpuscles) preceding spontaneous epileptiform seizures or during hyperventilation. He assumes that this abnormal lability is due to changes of ion-equilibrium as observed in hyperventilation. Since similar changes may appear in conditions associated with disturbances in the balance of the autonomic nervous system, it seems rather improbable that this abnormal lability of the plasma colloids is specific for convulsive disorders. Furthermore, it is not proved that the increased lability of the plasma colloids is able to influence the convulsive reactivity of the central nervous system. The changes in the state of the plasma colloids and those in the excitability of the central nervous system appearing in hyperventilation may have a common cause, such as disturbances in ion-equilibrium, but do not necessarily influence each other.

Changes of the Cellular Surface Films. The existence of a semipermeable membrane or surface film in nerve cells and fibers is indicated by the observation that the intact nerve cell or fiber is the seat of an electromotive force, a "current of injury" flowing from the intact to an injured part. According to the membrane theory, the cellular surface is semipermeable, allowing only some ions (*e.g.*, cations) to leave the interior of the cell,^{13, 132} so that a Helmholtz electric double-layer (*e.g.*, cations outside, anions inside) exists on the surface. Various stimuli induce excitation by changing the ion concentration on these surface films.¹²⁹ These changes in ion concentration act upon the cell membrane by transitorily increasing its permeability^{79, 107} and thus abolishing its potential in the stimulated region, so that an "action current" may be demonstrated flowing from a resting to an excited region. The local action currents between the depolarized region and its normal neighborhood act as stimuli to the next segments, and thus the nerve impulse is propagated by depolarization of successive segments of the nerve. In agreement with this

* According to E. Schiff and E. Roser [*Monatschr. f. Kinderheilk*, 19, 15, (1920)] in newborn infants during the first days of life the albumin content of serum runs up to 90 per cent of the total protein.

theory, Cole and Curtis²⁷ observed on single unmyelinated fibers of the squid, that the electrical conductance increases during the passage of an impulse. Spiegel and Henny^{100a} found that the convulsions following faradic stimulation of the brain are associated with decrease of its impedance (experiments on cats under superficial ether anesthesia). A similar change could also be demonstrated following single induction shocks applied to isolated, surviving frog's brains, where the disturbing influence of the circulation was eliminated, while such a change failed to appear in control experiments on dead brains.

Thus, the state of the surface films of the nerve cells and their fibers and their reactivity to the depolarizing influence of stimuli may be of decisive importance in determining the excitability and the conduction of impulses. It hardly needs to be emphasized that the state of the cellular surface and that of the cellular colloids are closely interrelated: on the one hand the permeability largely depends on the state of the colloids on the cell surface, and on the other hand changes of the permeability will affect the colloids in the interior of the cell.

Changes of the permeability of the ganglion cells seem to play an important part in the pathogenesis of convulsive disorders. Hypothetical views in this direction were expressed by various authors.^{53, 116, 157, 177} Inferences drawn from observations on serum colloids (Georgi) upon the state of the nerve cell membranes can be of hypothetical nature only. Since the effects of injection of dyes (*e.g.*, fuchsin,¹⁷⁷) into the circulation primarily depend upon the permeability of the capillaries, the results of injection experiments hardly permit one to evaluate the state of the cellular surface films. Spiegel and Spiegel-Adolf,^{162, 167, 168} therefore, tried to gain somewhat more direct information by taking advantage of the fact that polarization phenomena developing on semipermeable cell surface membranes depend upon the density of these membranes and may serve as an indicator of their permeability (see p. 1150). They demonstrated that in a number of apparently quite heterogeneous conditions causing convulsive disorders, decrease of the density of the cellular surface films represents a common basic mechanism. Such a reversible decrease could be demonstrated for conditions inducing hydration, *e.g.*, swelling of the brain *in vitro* (in hypotonic solutions, in alkali), or *in vivo* (intravenous injection of distilled water,* NaHCO₃, and NaOH respectively, alkalosis produced by hyperventilation). Such an effect can easily be understood if one bears in mind that swelling loosens the structure of a membrane by intake of water between its molecules or micelles.⁸⁹ The increase of the convulsive reactivity in conditions associated with swelling of the brain may partly be due to increase of intracranial pressure (see p. 1137). A decrease of the polarizability, however, could be found when swelling of the brain was induced by intravenous injection of distilled water with the skull trephined and the dura opened, so that increase of the intracranial pressure was prevented. When the skull remains closed, *e.g.*, in the convulsions appearing after administration of excessive amounts of water,¹⁴⁸ one has apparently a combined effect of hydration (plus increase of interstitial water) and increase of intracranial pressure upon the cell membranes. Similar conditions may prevail in certain cases of epilepsy, as shown by the beneficial effect of measures subtracting water from the body-tissue reservoirs,³⁸ and by the fluctuations of weight indicating retention of water before seizures⁴⁹ in a group of epileptics. The importance of water balance in some epileptics was strikingly demonstrated by McQuarrie and Peeler,¹¹⁷ who could induce convulsions in epileptic patients, but not in non-epileptic control subjects, by administering antidiuretic posterior pituitary extract (pitressin) during periods when the mineral intake was low while the water intake was unrestricted, so that a dilution of the extracellular body fluids resulted. Phasic disturbances of the water balance were also described in periodic psychoses.¹⁸⁰

A second group of epileptogenous agents, which impair the cellular surface mem-

* See page 1143.

branes in the cortex as well as in subcortical ganglia, is represented by those producing anoxemia, *e.g.*, experimental asphyxia. Brain anemia produced in most of our experiments an initial drop of the polarizability. When the anemia lasts for several minutes, the density of the membranes may again increase, probably because of coagulation necrosis of the cells.

The impairment of the cell membranes produced by increase of intracranial pressure probably also belongs in this group, since the increase of pressure is associated with cerebral anemia. In a number of instances, *e.g.*, in various conditions associated with brain swelling (see p. 1137) there is probably the combined effect of hydration and increased intracranial pressure, due to the increase of brain volume with the skull closed. Anesthetics and hypnotics may act in the opposite direction as the epileptogenous agents, *i.e.*, by rendering the cellular surface films more dense as could be demonstrated for ether or chloroform, intravenous injection of dial, or intraperitoneal injection of phenobarbital (see p. 1143).

It should be emphasized that decrease of the density of the cell membranes, as produced by hydrating measures, or by impairment of the oxygen supply to the brain, represents only one of the mechanisms by which epileptogenous agents act. A second mechanism is the local increase of ion concentration; if it is large enough it may induce convulsions, although the cell surfaces are normal. This is exemplified by artificial acidosis which may be associated with convulsions,^{36, 143} although according to our measurements it impairs the cell membranes only slightly, if at all. A similar mechanism may play a rôle in the genesis of hyperreflexia and of convulsions observed in dogs following intravenous injections of concentrated NaCl solutions.^{128a, 130a}

Measurements of the polarizability in the exposed brain of patients during operation seem to indicate that the experimental results obtained may be applicable also to the human brain. We found, for instance, low values in a case of vascular hypertension with increased intracranial pressure, and also in two epileptics. But the material is too scant as yet to permit definite conclusions. The fact that convulsions can be induced in epileptics but not in normal subjects by procedures that will result in dilution of the extracellular body fluids is interpreted tentatively by McQuarrie¹¹⁵ as indicating the existence of an inherent defect in the brain cell membranes in this disorder.

In dealing with patients who are repeatedly subjected to convulsions, one has to bear in mind that the repeated abnormal discharges of the brain cells and the associated vasomotor reactions may by themselves injure the brain cells and their membranes. In a study of the effects of convulsions induced by injection of metrazol, it was found that one single series of seizures of from 5 to 30 minutes' duration was able to diminish the polarizability of the cerebral hemispheres in guinea pigs.^{164, 165} After hypoglycemic shock with convulsive seizures lasting several hours the effect was still more marked.

An impairment of the cells of the human central nervous system following metrazol and insulin convulsions may be inferred from studies of the spinal fluid. Spiegel-Adolf and Freed¹⁷⁴ found in the spinal fluid of schizophrenics the ratio of the interferometric values of non-electrolytes to electrolytes (1NE:1E) higher after than before such convulsions; they interpreted these findings as indicating an increase of organic cleavage products in the spinal fluid following the convulsions. Similar changes were found following electrically induced convulsions in dogs.^{174a}

In earlier observations of Spiegel-Adolf¹⁷³ abnormally high values of this ratio were found in 60 epileptics, representing the only demonstrable pathologic change of the spinal fluid in this disease. In agreement with the assumption that this increase of the 1NE:1E ratio was due to an impairment of the cells of the central nervous system secondary to the convulsions, this ratio was the higher the more severe and/or the longer the convulsions were.

Conditions Influencing the State of the Colloids and of the Surface Layers of the Nerve Cells

Changes of Hydrogen-ion Concentration. In reviewing the effect of disturbances of the acid-base equilibrium we must bear in mind that in the central nervous system we are dealing with effects on protein-lipoid mixtures, while in other organs the effects are preponderantly protein reactions. While alkalis influence the swelling of proteins and lipoids in a similar manner, causing up to certain concentrations a steep increase in viscosity and hydration, the action of acids upon the state of hydration of proteins and that of certain lipoids is antagonistic: up to certain concentrations they increase the viscosity and state of hydration of proteins but decrease those of lecithin and cephalin; ^{68, 144, 169} the water-binding capacity of sphingomyelin is, however, pronounced in an acid milieu, according to Toennis.¹⁷⁹ Thus one can easily understand that alkalis distinctly facilitate the hydration of brain tissue, as could be shown *in vitro* by gravimetric methods¹¹ and *in vitro* and *in vivo* by the associated decrease of the polarizability,^{162, 168} whereas acids further swelling only slightly or not at all.^{11, 12, 181} Bauer even assumed that acids inhibit swelling; his results were, however, at least partly due to post-mortem changes.

Recent experiments in which the pH was varied by phosphate buffer mixtures¹⁵² showed a minimal increase of volume of rabbit's brain at the neutral point (pH about 7.40); the volume increase reached a maximum in the alkaline range (pH 7.6-8.3) within 2-3 hours, in the acid range (pH 6.00-7.30) beyond the 6th hour. After the 6th hour neutralizing processes in the tissue induced a retrogression of the volume increase. Using the diminution of the birefringence of the myelin sheaths as an indicator of the swelling of nerves, Spiegel¹⁵⁰ studied the effect of acids not only post mortem but also on surviving frogs' nerves. He found that addition of acids to diluted Ringer solution furthers the swelling only in concentrations that already impair the excitability. When acidosis was produced *intravital* in frogs by endogenous production of acids (Fischer's⁴⁰ method of uranyl nitrate intoxication), or by oral administration of acids in rabbits, the study of the birefringence failed to show a swelling of the myelin sheaths. In agreement with these findings, the decrease of the polarizability under the influence of acids was much less marked than that induced by alkalis^{162, 168} and production of acidosis *in vivo* failed to induce a definite decrease of the polarizability.¹⁶⁸ The swelling of the brain and decrease of its polarizability produced by alkali may be inhibited by immersion of the brain in acids; partial restoration of the former values may even be produced, particularly by acetic acid and tricarballic acid. Also *in vivo* the changes induced by an alkaline shift are reversible.

Effect of Other Ions. Swelling of brain tissue may be inhibited by cations in the order Ca, Ba, Sr, > Na, Li, > K, Cs, > Rb; and by anions in the order citrate > tartrate > oxalate, sulfate > acetate > CNS > Br > NO₂ > Cl > I.⁶⁵ Similar findings were reported by Ludlum *et al.*,¹⁰⁸ who observed also a shrinking effect of aluminum and magnesium chloride. In agreement with Haldi's experiments on the effect of ions on water absorption of brain tissue * Spiegel and Spiegel-Adolf found that sodium inhibits the decrease of the polarizability of brain tissue * more than does potassium, whereas lithium was more effective than sodium. Calcium inhibited the decrease of the polarizability as compared with sodium, and increased the density of the cell membranes in a swollen brain. Magnesium, however, had no inhibitory effect upon the decrease of the polarizability. In the group of the trivalent cations, lanthanum had a distinct inhibitory effect upon the decrease of the polarizability as compared with sodium, but aluminum had no such effect. After previous swelling of the brain its polarizability increased in NaBr solution more than it did in equivalent NaCl solution, contrary to the Hofmeister series, but in agreement with Haldi's experi-

* As to the effect of various ions on the polarizability of artificial membranes, see 171.

ments. The effect of bromides may be explained by observations of Spiegel-Adolf¹⁷² showing that the viscosity and refraction of lecithin-sols are more depressed by addition of bromides than by equal concentrations of chlorides. In accordance with Hofmeister's series, the polarizability decreased in NaI and NaCNS more than it did in equivalent NaCl solution.

Intravenous injection of hypotonic solutions or distilled water produce cerebral edema^{183, 184} and eventually also hydration of the nerve cells³⁹ associated with decrease of the polarizability.^{162, 168}

Anesthetics and Hypnotics. It is rather generally assumed that anesthetics and hypnotics act by changing the physicochemical state of the cells, particularly of their lipoids.^{123, 133} Also the hypnotic efficiency of the barbiturates seems to be related to their reaction with lipoids.¹⁷⁸ An important part in the mechanism of anesthesia is played by changes of permeability of the cell membranes. Such changes were studied by numerous investigators.^{52, 59, 60, 79, 107, 131, 186} A majority of them found diminution of the permeability under the action of the anesthetics on plant cells, eggs, and various tissues (skin, muscles, and peripheral nerves), as long as no irreversible injury to the cells with subsequent increase of the permeability was produced. Using polarizability as a measure of permeability of cell membranes, Spiegel and Spiegel-Adolf¹⁶³ extended such studies to the action of anesthetics and hypnotics upon the central nervous system *in vivo*. They found that ether, chloroform, chloral hydrate, and barbiturates increase the polarizability, indicating an increase in the density of the cellular surface films. This action is not limited to certain regions, since "cortex anesthetics"¹²⁴ such as ether, chloroform, and chloral hydrate have an effect upon the brain stem too, and a "brain stem anesthetic," such as dial, also acts upon the cerebral hemispheres. Because of the densifying action of anesthetics the cell membranes will become more able to resist the depolarizing effect of stimuli, which is an essential part of the excitation process (see page 1139), and thus the excitation threshold will be raised.

The finer mechanism by which anesthetics act upon the cell membrane escapes direct observation. The myelin sheath is, however, an object which permits one to study the effect of anesthetics upon surviving and still excitable nerves under the polarization microscope. It could be shown that the birefringence of the myelin sheaths of surviving frogs' nerves is diminished or abolished under the influence of anesthetics.¹⁶⁰ This is, at least under physiologic conditions, a reversible process; if one stops the anesthesia, the birefringence returns nearly simultaneously with the excitability. By using various concentrations, *e.g.*, of ethyl or methyl alcohol, it could be demonstrated that the effect of the anesthetics upon the myelin sheaths is antagonistic to that of water. It was inferred that narcotics try to displace the water that is in loose combination with myelin. As was pointed out by Winterstein, such a displacement of water may be explained by adsorption of the anesthetics to the cell colloids, which become surrounded by the narcotic. Such an adsorption to the lipoids will diminish their surface tension.^{15, 23, 180} This seems an important factor in the mechanism of the above-mentioned changes in the birefringence of the myelin sheaths. The optical axes of the myelin sheath normally lie perpendicular to its surface and quickly regain this position after the anesthetic is withdrawn, as shown by the return of the birefringence. In view of the relationship of the optic axes to the surface of the myelin sheath, it does not seem far fetched to relate their arrangement to the action of surface-tension forces. Conversely, it may be inferred that anesthetics (in decreasing the surface tension of the lipoids) affect the intermicellar forces which are related to the surface tension. It seems of interest in this connection that Handovsky⁶⁶ explains the changes in the x-ray diffraction pattern observed under anesthesia as due to changes in the arrangement of fatty acid molecules.

Winterstein¹⁸⁶ assumes that lipoids are no more important than other cell colloids in the mechanism of anesthesia, while others^{26, 107} emphasize the fundamental rôle

of the lipoids. It may, therefore, be mentioned that the index of polarization which we found changed under the action of the anesthetics, namely, the difference in conductivity at low and at high frequencies, could be imitated in studies on artificial bio-colloid membranes,¹⁷¹ but only by those membranes which contain lipoids (kephalin, lecithin) in fine dispersion.

The concept formed as to the action of the anesthetics on the lipoids of the surface layers of the nerve cells depends, of course, upon the notions one has regarding the structure of the cellular surface. Clowes assumes the existence of a balanced mixture of water-in-oil and oil-in-water emulsions. Anesthetics such as ether, chloroform, chloral hydrate, barbital, etc. when shaken with water and olive oil, give rise to droplets of water in oil (probably by lowering the surface tension of the oil more than that of water), and do not produce droplets of oil in water.⁷⁸ Water-in-oil formations also occur, according to these authors, when analgesic and antipyretic drugs (acetanilid, acetphenetidin, or acetylsalicylic acid) are used. Thus, Hirschfelder⁷⁷ assumes that the predominance of the water-in-oil emulsion seems to correspond to the "anesthetic and analgesic phase" in the surface layer of the nerve cells. In accordance with this view emulsions rich in the water-in-oil type are relatively impermeable to water and salts, as indicated by their low electric conductivity. Thus, the densifying effect of anesthetics may be well explained on the basis of this theory. It also gives an understanding of the magnesium-calcium antagonism discovered by Meltzer and Auer;¹²⁰ the anesthetizing magnesium salts tend to increase the water-in-oil phase of the emulsion in the cellular surfaces, while antagonistic calcium salts restore the normal proportion of the oil-in-water phase. Further experiments of Hirschfelder indicate that monovalent cations, particularly potassium, antagonize in a similar way the narcotic action of magnesium.

If we assume that the surface of the cells is formed by a continuous layer of lipoids such as lecithin and/or kephalin,^{69, 94, 107, 111} we may also understand the effect of anesthetics by their action upon the lipoids. We must bear in mind that such a layer of phosphatids would also permit the passage of water and salts under normal conditions, since these lipoids are able to take up water and to combine with cations (Koch), the lipid particles probably being hydrated, *i.e.*, surrounded by a layer of water. If the anesthetic becomes adsorbed on the lipid particles, it will displace this water and a decreased permeability for water and electrolytes will result. The above-mentioned calcium-magnesium antagonism, however, can better be explained by the concept of Clowes and Hirschfelder.

The action of the anesthetics will, of course, not be limited to the cell surfaces; they will also affect the state of the colloids in the interior of the cell. Winterstein assumes that the enveloping of the cell colloids by the adsorbed anesthetic inhibits the intake and discharge of metabolic products, and the action of ferments. Thus, the effect of anesthetics upon the metabolism of the cell, *e.g.*, the inhibition of the oxidative processes (oxidation of glucose, lactic acid, and pyruvic acid^{29a, 144a}), may be explained by the same basic reaction with the cell colloids as the increase in density of the cell surface.

Deficient Oxygen Supply. Disturbances of circulation associated with reduced oxygen supply may influence the state of hydration of the brain colloids, since products of metabolism such as lactic acid accumulate in the brain tissue and induce a change in its pH. While in anoxia due to reduced cerebral blood flow the cortical pH shifts in an acid direction, in anoxia resulting from breathing nitrogen there occurs a shift in an alkaline direction.¹⁷⁶ As we pointed out, alkaline reaction is conducive to hydration of brain tissue and increased permeability of the cell membranes, while acid reaction favors swelling of brain tissue to a lesser extent, if at all. Thus, one may understand that anoxic anoxia decreases the density of the cell membranes as indicated by measurements of the polarizability,¹⁶⁸ while the changes observed in cerebral anemia are more complex. In the majority of our experiments, at least

an initial diminution of the polarizability was observed; yet the polarization index of the cell membranes usually rose again during the occlusion of the cerebral vessels. One may perhaps infer that the local acidosis eventually induces a coagulation necrosis of the nerve cells. Histological observations seem to point in a similar direction, since Gildea and Cobb⁵⁸ report that shrinkage of the nerve cells and homogeneity of the protoplasm is the most frequent change following ligation of the cerebral vessels. For peripheral nerves the importance of oxygen supply for the state of polarization of the surface membranes may be inferred from the observation⁵⁴ that the membrane potential falls progressively during anoxia.

Neuropsychiatric disorders may be caused not only by insufficient oxygen supply of the central nervous system, but also by deficiencies in the ability of the cells to utilize the oxygen supplied. Deficiencies in oxidative processes in the cerebrum seem to play an important part in schizophrenia. This is indicated by the low content in neutral sulfur⁹⁶ and in catalytic iron; Freeman⁴⁵ found the latter deficient, particularly in the deepest layers of the frontal cortex in catatonics. The disturbance seems not to be limited to the cerebral cortex, however, as shown by the relatively poor reaction of the respiratory center to administration of CO₂ in the inspired air,⁶² and the low oxygen consumption, and nitrogen and carbohydrate metabolism¹⁸⁸ of some schizophrenics.

Endocrines. *In vitro* experiments of Haldi⁶⁵ and associates indicate that thyroxine does not alter the swelling ability of the cerebral hemispheres, while suprarenine bitartrate solutions seem to have a slight inhibitory influence. Page,¹³⁴ however, doubts whether these observations may be applied to conditions *in vivo*. In thy-mectomized dog's brain swelling was observed,⁹² which Liesegang¹⁰⁶ assumed was due to the associated acidosis. Such an explanation, however, seems improbable in view of the above-mentioned experiments on the influence of acidosis on the state of hydration of the brain. The hypoglycemia induced by insulin injection seems to be associated with hydration of the cells of the central nervous system.¹⁹⁰

Vitamins. The importance of hydrogen-ion concentration and of oxidation processes for the state of the brain colloids may also shed light upon the action of some vitamins. Vitamin B₁ deficiency seems to be associated with defective ability of brain tissue to oxidize lactic acid particularly.^{76, 139, 140} Vitamin A and its precursor carotene may play a role in the oxidative processes in medullated nerves, but the results of various investigators^{43, 125} are controversial. Vitamin C seems to act as an oxygen carrier and to promote tissue oxidation. Wortis¹⁸⁷ points out that the high respiration rate of brain tissue probably has some connection with its relatively high ascorbic acid content. In experimental scurvy ascorbic acid diminishes in the brain; this may induce cellular anoxemia which may partly account for convulsions in late scurvy (Wortis). Changes in the chemical composition of the cerebral hemispheres and of the cerebellum were found in scurvy by Palladin and Ssawron,¹³⁵ in that the water and total protein content was increased and the phosphorus content decreased. The importance of vitamin D for the state of the central nervous system is probably due to its influence upon the calcium metabolism, the calcium content of brain tissue decreasing 25-35 per cent of its normal value in rickets (Wortis).

Methods of Investigation and Their Application

Gravimetric Methods (Comparison of Brain Volume and Skull Capacity). The volume of the brain may be ascertained by determination of its weight and its specific gravity, and compared with the capacity of the skull, measured by filling the skull with water.¹⁴⁶ According to Reichardt, in normal adults the brain is 10-16 per cent smaller than the skull capacity; in children the brain volume is relatively larger. If an increase of the brain volume in relation to the skull is found, one must of course ascertain whether it is due to hyperemia, inflammatory processes, tumor, edema, or true swelling.

If one wants to ascertain the ability of the dead central nervous system or parts of it to swell in various fluids, the increase of its weight after immersion for some time in the test fluid may be used as an indicator.¹¹ Weil first dries the brain tissue in a vacuum desiccator at 60–80°—a procedure which does not change its water-binding power—and determines the difference in weight of the fresh and of the dried substance. This gives the water content of the organ. Then he immerses the dried substance in distilled water. After swelling it is weighed and again dried in the vacuum desiccator. The difference of weight before and after drying indicates the water-binding power.

Chemical Methods. While the determination of the difference in the weight of the fresh and of the dried organ yields information regarding its total water content, it fails to tell what part of the water is intracellular and what is extracellular (in interstitial spaces). This question becomes of importance if one wants to know whether an increase of the water content of the brain is due to true swelling (increase of intracellular water) or to edema (increase of interstitial water).

Determination of the electrolyte content, particularly of the sodium, potassium, chloride and phosphate content, may help to solve this problem and also yield information regarding the selective impermeability of the cellular surface films. Perfusion experiments on isolated muscles,¹²⁶ as well as experiments *in vivo*,⁷² indicate that muscles easily give off their sodium and chloride but retain nearly all their potassium and phosphate. The view seems, therefore, not unjustified that sodium and chloride are contained chiefly in the intercellular fluids, and potassium and phosphate in the intracellular fluids, and that the normal cellular membranes have a high selective impermeability to these ions. Such a concept was extended to the body in general.^{51, 71, 138} Since electrolytes are largely responsible for maintaining the osmotic pressure of the body fluids and consequently also for the distribution of the water, changes in the volume of the intra- and extracellular fluids may be estimated in the following way, based on the assumption that all brain chloride is extracellular.^{29, 71}

The volume of the extracellular water is calculated by dividing the total chloride by the concentration of chloride in the extracellular water; the latter is estimated by determination of the chloride concentration in the serum. The difference between the total water and the extracellular water gives the volume of the intracellular water. The product of the volume of the extracellular water and the concentration of potassium (or sodium) in the extracellular water (estimated from their concentration in the serum) gives the amount of the extracellular potassium (or sodium), and the difference between total and extracellular potassium gives the intracellular potassium. The latter value divided by the volume of the intracellular water equals the concentration of potassium in the intracellular water.

By using this principle, Yannet¹⁹⁰ arrived for instance at the conclusion that hypoglycemia first induces hydration and later shrinking of the cells in the central nervous system. In using the determination of the electrolytes for a study of the distribution of water in the central nervous system, one is of course faced with the problem whether the experiments on other organs, particularly on muscle, may be applied to the central nervous system. Amberson and associates⁴ found that cerebrum, cerebellum, and spinal cord retain their chloride tenaciously (contrary to peripheral nerves and other organs), if the plasma chloride is reduced to as low as 6 per cent of normal. They conclude that in the central nervous system a considerable fraction of chloride is intracellular. According to Yannet,¹⁸⁹ however, the brain cells adjust themselves to the depletion of extracellular electrolytes by releasing intracellular potassium in quantities proportional to the decrease in the concentration of extracellular sodium. He considers his data following depletion of extracellular electrolytes consistent with the view that all sodium and probably all chloride in the brain is diffusible. He explains the contradictory findings of Amberson and as-

sociates by their failure to allow adequate time for equilibrium to occur between brain and plasma before removing tissue for analysis. In agreement with the concept that in the central nervous system potassium is chiefly intracellular are the findings in cerebrospinal fluid, which has a composition similar to that of interstitial fluid; it contains rather little potassium (average, according to Mestrezat,¹²¹ 20.7 mg per cent) compared with its relatively high sodium content (average 322 mg per cent).

Optical Methods. Such methods are of particular interest, as they permit the study of the more intimate structure of the nerve cells and fibers in living or surviving preparations without the use of fixation or of stains, *e.g.*, examination with the ultramicroscope or under polarized light. After ultramicroscopic studies Auerbach⁶ and Marinesco¹¹² asserted that the axoplasm does not contain continuous fibrils, and that the finding of neurofibrils is an artifact produced by fixation methods. At the most, very small particles may appear under the ultramicroscope in the axoplasm arranged in longitudinal direction. Under the flocculating action of certain electrolytes a neurofibril structure may, however, appear.³⁷ Thus one may regard the living substance of nerve cells and fibers as consisting of a sol with rod-like particles and a tendency to longitudinal orientation of these particles.¹³⁷ On quite fresh material Peterfi was also unable to see these particles under the ultramicroscope; they may, however, appear and orient themselves in the longitudinal direction and form fibrils, if the preparation stands for some time, which reminds one of ageing sols. In the state of degeneration of the axis cylinder the Tyndall phenomenon may be seen (Marinesco). The use of the ultramicroscope in the study of pathologic swelling conditions in fresh brain tissue was recommended by Ludlum, Taft, and Nugent,¹⁰⁸ who observed by this means that less hydrous material has more definite edges and a more granular appearance than "wetter matter." The influence of various agents, *e.g.* the coagulating effect of anesthetics upon the colloids of the axoplasm, may be also demonstrated by the ultramicroscope (Auerbach). In the nerve cells (spinal ganglia) granules could be seen under the ultramicroscope; these are, however, not identical with the Nissl bodies (Marinesco). Peterfi was also unable to find Nissl granules.

Dark-field illumination may further be useful for a study of the distribution of minerals in the elements of the nervous system under normal and pathologic conditions on preparations obtained by microincineration.^{2, 105, 151} The results of microincineration may be supplemented by quantitative measurements with the aid of emission spectra. Alexander and Myerson determined the iron by the increase of the intensity of the iron line produced by the addition of a certain amount of iron to a weighed amount of the sample. By relating the intensity of the iron lines to those of the other elements studied, they were able by reference to calibration curves to estimate the amount of the element present in the sample.*

The study in polarized light centers chiefly about the myelin sheath in myelinated nerves.

The myelin sheath has a positive birefringence, the optical axes lying perpendicular to the longitudinal axis of the nerve. On a transverse section they show a radial arrangement. Thus the optical axes upon which the microscopic picture depends are perpendicular to the longitudinal axis of the nerve, simulating a negative one-axis birefringence in the direction of the longitudinal axis.^{5, 35} The axoplasm has a positive one-axis birefringence, as can be seen in unmyelinated nerves or after extraction of the myelin of a myelinated nerve.

The birefringence of the myelin sheaths is due to their glycerophosphatides.⁶¹

* The absorption spectrum of non-medullated nerves (the claw nerves of *Homarus* and *Limulus*) examined with the spectromicroscope presents two distinct bands characteristic of hemochromogen compounds; the hemochromogen present in these nerves does not react to reagents as does cytochrome. Medullated nerves (sciatic of green frogs) show two wide bands of the carotinoid pigments superimposed upon the general absorption of the phosphatids.¹²⁵

Under the influence of hydrating agents and of lipoid-soluble anesthetics, the birefringence is decreased.^{159, 160} These are, at least in the beginning, reversible processes. Of practical importance is the observation that the birefringence of the myelin sheath diminishes in the beginning of Waller's degeneration,^{7, 153, 154, 158, 182} since this change permits one to demonstrate injuries to the myelin sheath at an early stage. This diminution of the birefringence is at first also reversible; it precedes the chemical breakdown of the myelin.

The assumption that the birefringence of the myelin is due to a crystalline structure⁶¹ is supported by the x-ray diffraction pattern of myelinated nerves (see page 1149). In order to explain the typical arrangement of the optical axes of the myelin sheath perpendicular to its longitudinal axis, it seems necessary to believe that radial forces arranging the submicroscopic crystals exist in the myelin sheath, and that these forces are at least partly related to the surface tension. As was pointed out elsewhere,¹⁰¹ the reversibility of the decrease of the birefringence produced by hydration or by anesthetics can hardly be explained without the action of surface-tension forces. The decrease of the birefringence of the myelin sheath following severance of the axis cylinder remains unexplained, if one does not take into account the mutual relationship ("zygiosis") of surface tension in the axoplasm and myelin sheath. A possible relationship between birefringence and electrostatic forces has been suggested by Keller.

While the disintegration of the axoplasm following severance of a nerve may be explained by the loss of its connection with the cell body and its nucleus, the breakdown of the myelin sheath can not be understood on this basis, since it consists of segments separated by Ranvier's rings. In view of this fact the following physico-chemical explanation has been offered.¹⁵⁸ The differentiation of the neuron into a cell body and processes indicates the existence of differences in surface tension between the various parts of the cell. Cutting the nerve abolishes the action of these differences of surface tension, and the plasma of the axis cylinder tends to return to the spherical form. The relationship between the axis cylinder and the myelin that normally forms a cylindrical sheath around it may be compared to that of two immiscible fluids, A and B. According to Freundlich,⁴⁶ a drop of B will spread on the surface of A, if A (*i.e.*, the axoplasm in our case) has a greater surface tension than B (*i.e.*, the myelin). If the axoplasm disintegrates into numerous spheres, this relationship of the surface tensions is disturbed, and the myelin also tends to return to the spherical shape. These physical changes are first manifested in the decrease of the birefringence and precede the chemical disintegration of the myelin which is demonstrable by the Marchi method. It should be emphasized that these chemical changes cannot be explained by the above-mentioned physical mechanisms alone. One might surmise that they are caused by products (enzymes?) liberated during the breakdown of the axoplasm. These problems, however, require further study.

Microscopic staining methods may be utilized for a study of electrical potentials in the elements of the nervous system. Keller⁹¹ groups the histologic stains, according to the direction in which they are carried by the electric current, into anodic and cathodic stains, and uses them for determination of the morphologic distribution of potentials. He finds, for instance, that the membrane of the nucleus and tigroid bodies are negative, the elements appearing as neurofibrils are electro-positive; the inner surface of the myelin sheaths is negative; their Lantermann-Schmidt-Golgi structures are positive; neuroglia and collagen fibers negative.

X-ray Diffraction. The results of studies under the ultramicroscope and in polarized light were supplemented by the x-ray diffraction method.^{16, 66, 75, 90, 147, 150} By using an exposure time of only eight minutes, Boehm studied surviving nerves in a moist chamber. From a comparison of the diffraction patterns of various peripheral nerves (myelinated nerves with oriented lipoid, unmyelinated nerves with and with-

out oriented lipid, nerves without definite lipid), Boehm concluded that in the myelin sheaths the geometrical longer axis of the liquid crystalline structures is perpendicularly oriented to the direction of the nerve. This seems in agreement with the above-mentioned results of the studies in polarized light. It should here be recalled that polysaccharides and proteins behave differently, the longer axis lying parallel to the fiber axis; conditions in the myelin sheaths can be imitated, according to Thiessen by silk threads drawn through soap solutions. The oriented material in myelin sheaths is described as mixtures of cephalin and cerebrosides, with an average molecular spacing of approximately 4.8 Å. The amount of connective tissue varied considerably in the different peripheral nerves. In agreement with the results of ultramicroscopic studies, Boehm asserts that neurofibrils do not exist in the living nerve, and that the axis cylinder is a tube filled with an amorphous and viscous jelly. The water in the connective tissue of nerves is partly bound within the micelles. The effect of stimulation is controversial. While Boehm was unable to detect changes in the x-ray diffraction pattern of peripheral nerves even on strong faradic stimulation, Handovsky reports changes observed in the spinal cord of frogs after electric stimulation or strychnine poisoning. Both authors agree that narcosis modifies the x-ray diffraction pattern; this change is explained by action of the narcotics upon the lipoids (change in the arrangement of the fatty acid molecules, Handovsky).

Schmitt, Bear and Clark, using x-ray beams of longer wave-length, further elucidated these problems. They found in dried nerve fibers spacings which closely corresponded to those of extracted lipoids, lecithin and cholesterol. But the equatorial sickles at 11.5 Å, visible in fresh nerve, cannot be reproduced by the extracts. The dimensions of the fundamental aggregate of the liquid crystals of the fresh myelin sheath are given as $4.7 \times 9.4 \times 171$ Å. In human brains Reynolds, Corrigan and Hayden found some differences between gray and white matter of the cerebrum which became more appreciable upon drying. Orientation was found in nerve trunks but not in the white matter, where it could be detected only by studies of birefringence in polarized light.

Measurement of the Conductance and Polarizability

Measurements of the conductance of the exposed brain *in vivo* were performed by neurosurgeons,^{63, 104, 122, 136} using a Wheatstone bridge arrangement. Since the conductance of normal brain tissue (cerebrum 1.8×10^{-3} mho, cerebellum 1.53×10^{-3} mho, with Meyer's electrodes) is distinctly different from that of tumors (about $3.3 - 5.0 \times 10^{-3}$ mho), this method may be used as a help in determining the seat of a tumor during operation. The conductance of the brain *in vivo* depends to a large extent upon the variations of its blood supply, since the conductance of blood (6.6×10^{-3} mho with Meyer's electrodes) is about 4 times that of brain tissue.

In order to obtain a sharp minimum on the Wheatstone bridge, it is necessary to use alternating currents of sinusoidal wave form, such as are generated by vacuum-tube oscillators (see^{87, 88, 119}), and to balance not only the resistance but also the capacitance of the tissue (see p. 1150). The resistors used should be free of capacitance and inductance, and proper shielding and grounding of the bridge is essential particularly if higher frequencies are used (see⁶⁴).

In order to obtain more complete information about the state of the tissue, particularly of the cells, the determination of the conductance alone is not sufficient. As was already mentioned, fluctuations in the blood supply occurring *in vivo* produce considerable alterations of the conductance. In post-mortem measurements (Crile, Hosmer, and Rowland²⁸ on rabbits) this disturbing factor is more or less eliminated. It is, however, still difficult to interpret differences of conductance obtained under various conditions, since such differences may be due to changes in the ion concentration of the intra- as well as of the extracellular fluids, or of the permea-

bility of semipermeable cell membranes. Some information about the condition of the latter may be obtained by measurement of the polarization phenomena appearing if electrical currents flow through the tissue.

Since the cell surfaces are impermeable for certain ions, forming Helmholtz electric double-layers,¹⁰¹ a current flowing through the tissue will produce accumulation of ions on the semipermeable membranes and a counter electromotive force is formed. This becomes apparent as the polarization current if one interrupts the original current. Thus polarizable tissues act like condensers, showing a certain capacity (polarization capacity⁶⁰). If one measures the conductance of a tissue, one deals not simply with an "ohmic" resistance but with an impedance (Z) consisting of a true ohmic resistance (R) and a capacitive reactance (X): $Z = \sqrt{R^2 + X^2}$. Therefore, in order to obtain absolute balance on the bridge, one has to compensate not only the resistance, but also the capacitance of the tissue which creates a phase difference between current and voltage. This may be done by a variable condenser connected in series or in parallel with the balancing resistance. The capacitance necessary to balance the bridge may be used as a measure of the polarizability of the tissue and of the state of the cellular surface films.⁶⁰ Or one may determine the ratio of the reactance to resistance which represents the tangent of the phase angle (ϕ): $\tan \phi = \frac{X^{18, 26a, 110}}{R}$. If one uses high frequencies, the cell membrane offers rather little impedance to the current, and the ohmic resistance of the cell interior is mainly measured.^{60, 79, 119}

In these measurements of the polarization capacity or of the tangent of the phase angle it is necessary to obtain absolute balance on the bridge; and since each determination requires some time, it is rather difficult to record by this method quick changes of polarizability following experimental procedures *in vivo*.

Spiegel and Spiegel-Adolf^{162, 165} therefore used another polarization phenomenon as a measure of polarizability in brain tissue, *viz.*, the fact that the conductance increases with increasing frequency of the alternating current, in brain tissue as well as in other organs. They determine the conductance at a certain high (K_h) and at a certain low frequency (K_l); the difference, expressed in percentage of the conductance at the low frequency, is called the polarization index: $\Delta = \frac{K_h - K_l}{K_l} \times 100$.

It was demonstrated by quantitative studies on artificial membranes¹⁷¹ and on frogs' skin¹⁶⁶ (comparison of changes of Δ and of the dialysis of substances through these membranes) that measurements of Δ can be used as an indicator of permeability changes. A drop (rise) of Δ indicates lowered (increased) polarizability and thus increased (decreased) permeability of the cell surfaces.

Upon a similar principle is based a method to measure the thickness of the plasma membranes of single cells. The difference between the impedance at low frequencies and at frequencies over one million has been determined.^{118, 141} This method, however, has not yet been applied to the central nervous system.

Hydrogen-ion Concentration. A method for recording the pH of the cerebral cortex *in vivo* was described by Dusser de Barenne, McCulloch and Nims.^{34, 130} The authors use a glass electrode of the MacInnes type in conjunction with the microvoltmeter described by Burr, Lane and Nims.²² A marked alkaline shift of the cortex could be produced by intravenous injection of sodium bicarbonate as well as by hyperventilation; a marked acid shift by venous injection of a dilute acid, by hypoventilation, or by ether anesthesia.

A low (high) pH is associated with low (high) electric activity, as shown by the electrocorticogram and also by decreased (increased) excitability of the cortex. It seems that the variations in excitability with pH are sufficient to account for the changes in the electrocorticogram. Electrical stimulation of a focus producing after

* For measurement of the impedance see Horton.^{82, 83}

discharge, as seen in the electrocorticogram, results in acidity not only in the stimulated area but also in distant foci that are functionally related to the stimulated area, so that after-discharge appears in them also.

If a "central" epileptoid discharge of the cortex is produced by intravenous injection of camphor, the record of the cortical pH shows an alkaline wave followed by an acid swing independent of the record of the pH of the blood, which presents a steady, slow acid shift.³³

Microinjection may be used for the study of intracellular hydrogen-ion concentration, as was shown by Chambers and Pollock,²⁴ on the giant nerve cells of the medulla of *Lophius* (goose fish). Similarly, as in other cells, a hydrogen-ion gradient between cytoplasm (colorimetric pH about 6.9) and nucleus (pH 7.6 or above) was found.

Electrical Activity. A detailed description of the technique and application of electroencephalography is beyond the scope of this paper. We limit ourselves therefore to some general considerations of its relationship to physicochemical problems, and refer the reader for further details to the numerous excellent reviews in this field.^{14, 31, 56, 86, 99}

Since the cell membranes are the seat of electrical potentials, the fluctuations of potentials that may be led off the various parts of the central nervous system may be considered from a physicochemical point of view as due to changes in the state of the membranes of cells or cell groups. Conversely, it may be expected that a study of the electrogram may serve as an indicator of the physicochemical state of the cells concerned. However, we must be rather careful in drawing such conclusions; we must, for instance, bear in mind that a reduction of electric activity may be the result of an increase in density of the cell membranes, or of an increase of permeability to such an extent that potential differences can no longer develop. In general, it may perhaps be stated that the easier the cell membranes respond to the depolarizing effect of stimuli, or the higher the state of "spontaneous" excitation of the cells, the more pronounced will be the fluctuations of potential; this will be particularly seen as an increase in frequency of the potential waves of the electrogram, in some instances as an increase of their amplitude. There is occasionally an inverse relation between frequency and amplitude, fast oscillations being associated with small, and slow oscillations with large amplitude. Conversely, the less the cell membranes will respond to stimuli, or the more their spontaneous activity is depressed, the smaller will be the electric activity and the slower waves will predominate. The most pronounced example of increased electric activity is seen in convulsions in experimental animals⁴¹ or in patients.⁵⁷ Slow waves may be found in many conditions of depressed activity: in normal sleep,^{19, 30} or during the influence of hypnotics;^{20, 156} in various forms of impairment of the cells of the central nervous system, as in anoxemia;^{21, 103} in increased intracranial pressure; and in local injury of the brain substance, *e.g.*, due to tumors.¹⁸¹

It seems of interest that quite a considerable degree of spontaneous oscillations may be picked up, not only from the cortex,^{1, 10} but also from the thalamus,¹⁵⁶ when consciousness is so diminished that its outward manifestations are abolished. Thus some degree of neural activity may still be maintained in the prosencephalic as well as in the diencephalic centers upon which consciousness depends, even if the state of consciousness is so far depressed that spontaneous movements cease.

In studying the effects of a certain agent, *e.g.*, of certain ions or drugs, we must bear in mind that opposite effects may be obtained, depending on the dosage or the duration of the action of a substance. In general, on application of small doses or in initial stages of an intoxication, we observe an increase of the electric activity; while on prolonged action or immediately on application of large doses, the electric discharges may be depressed, as could for instance be demonstrated for potassium chloride, CO₂, and acetylcholine.^{17, 55}

A consideration of these quantitative factors may explain some controversial observations recorded in the literature.

Psychiatry

SEYMOUR DEWITT LUDLUM, M.D.

Gladwyne Research Laboratory, Gladwyne, Pa.

A definite physiological pathology of mental disease emerges when the chemical proportions of the blood proteins are plotted against the relative reactivity of the various physiological systems. These have a definite relationship, and the mental symptom may, without scientific faltering, be considered as simply another symptom of a definite physiological state. Terms that indicate the phenomenon as a disease entity, such as dementia praecox or manic depressive insanity, are quite unnecessary when it may be considered that such and such an amount of dynamic and proper conditioning of mind emanates from the proper optimum physiological, colloidal, and chemical states. Therefore, the psychological diagnosis under the present nomenclature in psychiatry, to be properly applied, must have the physiological chemical basis of symptoms to establish the structure of the psychosis.

A reversibility, in either direction, of the protein pattern from that to which the individual is accustomed, and at the same time a change in the physiology, in either inhibition or excitation, result in changes in brain function. These are dramatic

when observed for the first time, and become more and more interesting as the principle is seen developing in the various phases of mental disease.

The example of a person with repeated attacks of insanity characterized by confused manic episodes is given to show what takes place. In intervals of the disease this person exhibits a normal protein pattern of approximately albumin 65 per cent, pseudoglobulin 17 per cent, euglobulin 18 per cent, or figures within the normal band, and with normal physiological reactivities in temperature, Schilling hemogram, sedimentation, and the aggregation-dispersion phenomenon. He will run along in good physical and mental equilibrium for a year or more; then suddenly the albumin fraction will jump to 80 per cent, the pseudoglobulin will not change very much, but the euglobulin will become very low, and simultaneously all of the physiological symptoms enumerated above will recede to subnormal positions (Fig. 1, B). This reversibility of the chemical and physiological we have observed and charted a number of times, and each time the mental disorder of a confused manic state appears.

Another interesting point is that here is a rather sudden reversion to a type of immaturity (Fig. 1, A). This type of immaturity *per se* is very common. Constitutionally inferior persons (A) always have the chemical imbalance of high albumin and low euglobulin, as well as a subnormal physiology: subnormal temperature, leucopenia, with lymphocytosis, slow sedimentation, and the dispersion phenomenon in the blood drop. When living in this milieu they do very well, until subjected to excessive strain of environment or to infection, or to the adolescent, climacteric, or involutional states; then there is a moderate increase in the euglobulin and a slight reduction in the serum albumin (Fig. 1, C). It is almost as though they could not stand the rise in the euglobulin fraction, the effort of reactivity being too much, quite as though they were allergic to any increase in euglobulin. They can live in the chemical and physiological state to which they were born, but any stimulus requiring more of them results in a mental and physiological disorder. It is in this group that the cases that we call dementia praecox are induced; but we are really dealing with a constitutional state.

Charles Féré quotes J. Hunter¹ ("Oeuvres Complètes") as maintaining not the existence of a hereditary malady, but only a hereditary disposition to its contraction; and Féré² himself maintained that the predisposition is constituted by a state of degeneration, often characterized by gross anomalies of development.

W. Horsley Gantt,³ in writing about Pavlovian work, says that the important things in evaluating the conditioned reflexes are the constitution of the individual and the strength of the stimulus. Constitution would be the hereditary disposition. In fact in all processes of disease or in the study of inhibition or excitation in any living thing, the fundamental factors are the constitution of the organism and the characteristics of the stimulus.

In this essay it is the purpose to show that the constitution is characterized by a ratio between the serum albumin and the serum euglobulin of the blood, and that proportional to their ratio is a correlated integration of reactive qualities of physiology, in temperature, hemogram, sedimentation, blood pressure, capillary tonus, and aggregation and dispersion in the colloidal sense as seen in the fresh blood viewed under the ultramicroscope, described later.

This study has been made in the field of insanity, and what can be shown in resumé are these facts:

I. That there are immature constitutional states characterized in the blood serum by a high percentage of albumin fraction and a low euglobulin fraction, and depending upon their ratio there will be found varying non-reactivities in the above-mentioned physiological characteristics (A in Fig. 1).

II. That those persons who have good proportional protein patterns and adequate physiology but who suddenly go insane, as in the manic depressive type, either depressed or maniacal, suddenly become throw-backs; their serum albumin goes up,

FIGURE 1a.

their euglobulin down, and their physiology becomes non-adequate and non-reactive in temperature, white cell count, Schilling index, blood pressure, capillaries, aggregation and dispersion, thus producing a picture identical with that shown in A of Fig. 1. This is not a hereditary deficiency in protein pattern, as in the first instance, but there is an instability of the molecular constitution which controls the differential protein level. This unstable type reverts to immaturity (B, in Fig. 1).

III. Those persons who by nature present high albumin and low euglobulin fractions all the time, as in A, become insane when any effort is made to throw them into more activity or into less activity, a divergence from the level in which they are accustomed to live. They can remain comfortably in a state of immaturity (C in Fig. 1).

So in any instance or level of pattern, with any departure from their optimal concentrations or their level of equilibrated physiology, the higher functions of the

This is a very simple explanation of insanity, but not much imagination is required to realize that when there is this change in all the physiological characteristics mentioned, the additional symptom of mental aberration would result.

And Barcroft⁵ sums up in his book, "Brain and its Environment": "It would seem therefore that in the case of oxygen concentration there is simply a certain optimal concentration in the blood plasma, that to which we are accustomed, and if there is any gross departure from this on either side the higher functions of the brain suffer, leaving the lower ones either to run riot or to flag as the case may be." And in writing about CO₂ concentration effects,⁶ he says that both increased and decreased concentrations of CO₂ produced effects, and again the optimum in the natural fluid environment of the nervous system is necessary. Anoxia would be a natural expectation as a result of the physiological non-reactivity described in the preceding instances.

The word *optimum* brings to mind the state of the fluid environment of optimum colloidalilty. The essential necessity for normal functioning is so aptly stated by Alexander ⁷ in Vol. I of this series: "Figuratively speaking, if all the chemical substances comprising our organism were in true or crystalloid dispersion, reactions would proceed so rapidly that we would, so to say, live ten years in ten minutes. . . . Every organism is dependent upon the coordination of its chemical reactions *in point of time*, and this leisurely procedure depends largely on *degree of dispersion*, which keeps chemical reaction velocities within certain speed limits through its regulation of free surface and kinetic activity. Life lies between lysis and coagulation. The colloidal zone is, as it were, a vital metronome tolling off the tempo of life."

There are evidences of this sort in the blood of the insane person, seen by examining a drop of fresh blood in an ultramicroscope. The position of the red blood cells, one to the other, is one of aggregation or dispersion. This is also seen in the chylomicrons in the blood serum. It could be explained in the way Francis Schmitt⁸ explains the phenomena of the growth processes of cells; and he has done it experimentally with blood cells; that is, he has produced aggregation with Ca or histone and dispersion with cephalon. With Ca or histone there is dehydration and the charge is reduced, whereas with cephalon there is hydration and the charge is increased. Charge and hydration are the fundamental factors in colloid chemistry, according to Kruyt.⁹

These phenomena, as seen ultramicroscopically in the blood of sick people, are what is meant by aggregation and dispersion under the groupings of the physiological symptoms mentioned heretofore as changing in proportion to the ratio of albumin to euglobulin, so that undoubtedly there is a distinct colloidal phenomenon present as part of these physiological changes, as shown in Fig. 2. This is a phase of the under-

FIGURE 2. Phenomena of Aggregation and Dispersion. Fresh Blood Drop under Ultramicroscope.

lying physico-chemical state in health and disease which warrants much more study.

Suranyi has noted the same exhibitions by red blood cells, and they have been noted by other authors in the study of lipoids, cholesterin producing aggregation just as calcium and histone, and lecithin acting like cephalon.

Gildea¹⁰ has shown an increase of cholesterin in the manic depressive cases, which cases from our point of view would be the unstable group described as Fig. 1, B, and a lessening in schizophrenia, which is to be expected in the cases here described as non-reactors.

Bancroft¹¹ was perfectly right in considering that aggregation and dispersion in the colloid sense have a bearing on the physiology of insanity. But there is more than that fact alone. There is the influence of the protein state, the lipid state, the pH, and other factors affecting the colloid state. Another interesting phenomenon to be seen by ultramicroscopic examination of the serum, is a clearness or an opalescence, which varies with the proportion of albumin to euglobulin. All very much as Michaelis says happens to an aqueous soap solution when an amount of NaCl is added to bring about a strong opacity; and if there is then added a small amount of

CaCl₂, the opacity becomes less. This is good colloid chemistry and is important in studying the physico-chemical phenomena as they appear.

Group 1: Normal group.

Percentages: albumin 60-65; pseudoglobulin 15-20; euglobulin 15-20.

Group 2: Percentage of euglobulin 20 or more.

Group 3: Percentage of pseudoglobulin 22 or more.

Group 4: Percentage of albumin 65 or more.

These findings show that these mental cases fall into four definite groupings.

Group 2 is characterized by high euglobulin percentage and correlates immunologically with reaction to infection. Group 3 is characterized by high pseudoglobulin percentage and correlates with reaction to poisons, such as toxins from diseased organs like cirrhosis. These two groups, 2 and 3, are termed *hyper-reactor*, in the immunological sense.

Group 4 is characterized by high albumin percentages and correlates immunologically with the *non-reactor* type.

Group 1 contains those cases not falling within the other characterizations, but showing disturbance of the physico-chemical characteristics, specific gravity and viscosity, and it is termed *normal protein*.

More and more cases have been examined at the Laboratory during the period following the publication of 500 cases.¹² The methods used were based on the Kjeldahl, as described in the first publication.¹³ The findings of the later cases have been assembled, and the four groups are always found to exist.

From these tables inferences can be drawn relative to the proteins. The square blocks around euglobulin in one group, pseudoglobulin in another group, and albumin in still another group, indicate how the cases fall. The averages can be considered as very instructive, because the averages in large groups of figures do not show important variation; but as these tables of averages do show these distinct groupings, it becomes evident that there were a great many cases with excessive values to make the averages sufficiently high to produce distinctive groups. To demonstrate characteristic patterns, frank cases must be studied clinically and with physiological systems.

The albuminous group are the non-reactors, and with them mental degeneration comes on much more easily. Here most of the precocious dementias appear, people who cannot stand the strain, who cannot go through with adolescence or the climacteric. The highly albuminous person does not necessarily go crazy, but when strain comes, he does not adequately meet it physiologically or psychologically. These are the cases described in A and C of Figure 1.

The globulinous groups are the hyper-reactors, immunologically, those of toxic origin, poisons, liver, degenerations, infections. All of these cases show a globulin increase. There is a probable increase in antibodies in the globulin fraction and an untoward increase in the excitator chemical molecules, so that their work of growth, resistance, and repair are overdone, and the result is a poisonous disintegration or an allergy.

We are brought face to face with this fact: infection can bring on a mental disease; but an intercurrent infectious disease like boils, pneumonia, or erysipelas can cure a mental disease. Some years ago abscesses were induced as a curative agent. It is no uncommon thing to observe mentally sick people recover during an attack of boils. This shows a relation to the principles of immunity, very much like treating infection with a non-specific protein. Other people who become mentally ill following an infection are probably sensitive to some molecules in the increased globulin reaction to the infection. They are possibly allergic to any increase of their own euglobulin. It is just as injurious to them as too much activator substance is to plants or protozoa.

There is something in this albumin-euglobulin relationship that is very akin to the stimulator-inhibitor system postulated by Dr. J. B. Murphy in cancer research and by Dr. V. du Vigneaud in the egg white (avidin) and egg yolk (biotin) relationship. With an increase in the albumin proportion there is an increase in the inhibitory mechanism; and, on the other hand, with an increase in the euglobulin fraction there is an increase in the excitatory mechanism.

An examination of the principles of immunity reveals a number of points of interest, for there is a common ground in the position of the euglobulin and the physiologic reactivity, and recovery.

Why, in the acutely insane, do the physiologic reactivity and adequacy become depressed and the euglobulins go lower, and why, in those prone to dement, are they low to begin with? It is as though that formulation represents a regression to immaturity and a degeneracy.

Zinsser¹⁴ says in his "Immunity Principles": "The capacity to form antibodies is weak or absent in very young animals and only becomes fully developed as the individual seems to be fairly well established. In man, too, the production of antibodies appears to be less marked in infants than in older children." He quotes Lewis and Wells,¹⁵ saying: "The blood serum of young animals is deficient in globulins which, as we shall see, are closely associated if not identical with antibodies, and at first they apparently lack the capacity to form these proteins."

Zinsser also says that Locke¹⁶ notes significant variations in time required for the individual rabbits to return to normal temperature following immersion in cold water. The speed with which this warming up process takes place, runs parallel with the ability of the rabbit to resist intravenous infection with small number of virulent pneumococci.

The fact that we find proteins in arrangement similar to those found in other diseases, and that the warming up process in some rabbits is delayed, brings immunity reactions and physiological reactions closer together, and it could almost be said that these acutely insane with the non-reactive physiologic symptoms and the high albumin and low euglobulin have reverted to an immature stage in physical life.¹⁷ This applies to those cases which are non-reactive and not, of course, to those cases where there is gross infection with increased temperature and white cell count, and with aggregation and rapid sedimentation.

This correlation theme can be carried much further: with subjects such as time, the relation of chemical time and physiological and diurnal time, as has been suggested by Carrel, and du Noüy, and Hoagland; and with specific substances of growth like the auxins, or biotin, or avid albumin (avidin): or the values of different factors like pH and salts; the colloid osmotic pressure and its relation to capillary pressure; and to the relation of oxygen to cerebral function. But to avoid overstatement, this essay simply draws attention to the concurrent evidence that changes in the albumin-euglobulin ratio have a relation to physiological reactivity, which is a chemical relation to a physiological function, and then to the possible relation to immunity, and a most interesting relation to cerebral function and psychology.

The psychiatric terms, dementia praecox, schizophrenia, manic depressive insanity, are of doubtful accuracy in the diagnosis of mental disease. With the protein estimation and physiological reactivity as a basis from which to evaluate the psychopathologic reactions, a better understanding of mental cases can be obtained than by using the ordinarily recognized classifications of mental disease; and a much wider avenue of therapeutic approach is opened. In fact, by establishing the relation between proteins and physiology we indicate that each individual has a normal pattern which is peculiarly his own, and from which he departs in sickness and to which he returns in health.

There is a certain optimal relation of protein and physiologic reactivity to which an individual becomes accustomed; if there is any gross departure from this level either way, there is a disturbance of the higher functions of the brain.

Changes in the Surrounding Medium Produced by Free-living Cells

H. S. JENNINGS

University of California, Los Angeles

Single free-living cells, or Protozoa, in many cases modify the immediately surrounding medium by means of emanations from the cell. The unicellular organism is thus enveloped in an aura, or a modified zone. Such modified zones play striking rôles in the natural history of the organisms.

The existence of such an aura is known mainly from the reactions of other individuals that approach the cell in question. As the chemical or physical nature of the cell emanation is known in relatively few cases, the phenomena present a set of problems for physicochemical investigation.

Since the free-living cells which show these phenomena live in water, the cell emanations are as a rule in watery solution. Many of the organisms are complex in structure and function, having organs (or "organelles") of motility, of nervous conduction, of nutrition and excretion, and of reproduction. They resemble miniature machines, rather than undifferentiated bits of colloid material. Yet each is organized as a single mass of cytoplasm with a central dominating nucleus (or in some types with an additional minute reserve nucleus or "micronucleus"). They are therefore commonly considered to be single cells.

1. The existence of an aura or modified zone about Protozoan cells is shown in a most striking way by the assembling of many individuals in a small area (Figure 1). These phenomena have been most studied in species of *Paramecium*.

FIGURE 1. Spontaneous groups formed by *Paramecia*. A and B, successive stages as the groups grow larger. (After Jennings 1906)

If water in which individuals of *Paramecium* are scattered is placed on a plate under a cover glass, so that the organisms are swimming about in a thin layer of water, the phenomena are shown conspicuously. After a time the individuals are seen to

have begun to collect more densely in a small area. The collection enlarges and becomes more densely crowded, so that in time a close aggregation is formed in this area, while the remainder of the water is left with few or no individuals. Similar aggregations, a little less sharply defined, are formed when the organisms are placed in test tubes or in vessels of any form (Figure 2).

FIGURE 2. Spontaneous groups formed by *Paramecium*, under different conditions. A, on a glass slide, under a cover glass. B, in a test tube. C, in the bottom of a watch glass. (After Jennings 1906)

In these aggregations the individuals are seen to swim about freely. But on coming to an invisible outer boundary of the area, each individual turns back and remains in the area. This boundary at which the individuals turn back is definite and sharply defined. Individuals that are outside this area are swimming about freely in all directions. When the course of such an individual carries it to the outer boundary of the area of aggregation, it crosses this boundary freely and without reaction. But after coming thus within the area it reacts and turns back at coming to the outer boundary, so that it remains within the area. Thus every individual that enters the area remains, so that after a time a dense aggregation is formed. The course of any single individual entering the area, and remaining, is like that shown in Figure 3.

FIGURE 3. Path followed by a single *Paramecium* in entering and remaining in a region of weak acid, as in a spontaneously formed group. (After Jennings 1906)

Observation shows that these aggregations begin by the chance meeting in a certain spot of two or three individuals. This commonly results from the fact that the organisms react to a small solid or to a roughened surface by settling against it

and remaining quiet. Two or more individuals thus settle in a certain region. This region then becomes an "attractive" area, into which other individuals enter by chance, and remain in the way just described.

In the case of *Paramecium*, tests made with sensitive indicators show that fluid of the area in which the organisms collect has a faintly acid reaction, while the remainder of the fluid in which the animals live is commonly slightly alkaline. It is at the boundary of the acid region, where the swimming individuals would pass into the alkaline fluid, that reaction occurs, the individual turning back into the acid.

By introducing with a fine pipette a bubble of carbon dioxide, or a minute drop of water impregnated with carbon dioxide, an exactly similar aggregation can be produced, the animals gathering and behaving just as in the spontaneous aggregations (Figure 4). The carbon dioxide solution is of course faintly acid (carbonic

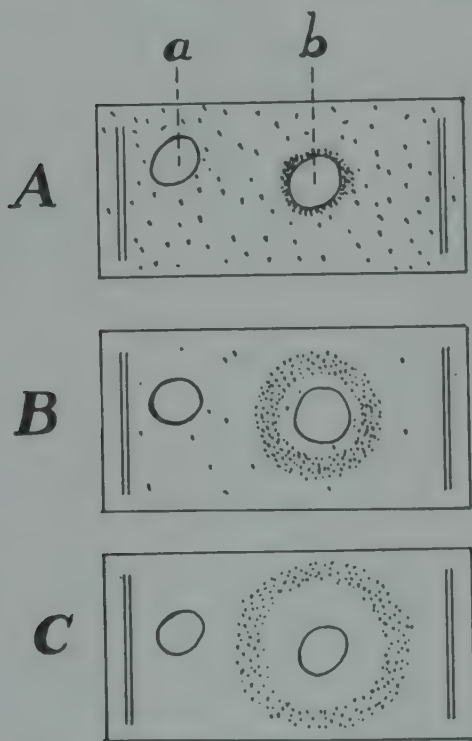

FIGURE 4. Collection of *Paramecium* about a bubble of CO_2 , at *b*. At *a* is a bubble of air; the infusoria do not collect about it. A, B and C, successive stages. In B and C the infusoria collect in a ring at a little distance from the bubble of CO_2 . (After Jennings 1906)

acid). The animals enter it freely and refuse to leave it, just as they do in the spontaneously formed groups.

Paramecium like other organisms, forms carbon dioxide in the respiratory processes, and this must diffuse into the surrounding water. This appears to be the secret of the spontaneous aggregations. As the individual gives off carbon dioxide, it becomes surrounded by an aura of that substance, having acid properties. Another individual swims by chance into this region and reacts in the way described, refusing to leave the acid. Its own carbon dioxide production is added to that of the original individual, so that the acid area becomes larger and more potent. Other individuals enter, and the area of aggregation continues to grow.

Experimentation shows that the aggregations in the case of *Paramecium* are due to the properties that are common to all acids, resulting from the presence of hydrogen ions. For weak acids of any kind induce aggregation, just as does the carbon dioxide solution.

If the acidity of the solution is sufficiently increased, the stronger acid repels the organisms. They refuse to enter it, just as they refuse to enter alkaline regions, so that an area of stronger acidity is left empty. This phenomenon is seen also in

the spontaneous aggregations. When such an aggregation has become very dense, the organisms begin to avoid its central parts. They remain in an outer ring in which the acidity is of optimum degree. Here they swim about, reacting negatively at both the inner and the outer boundary of the ring (Figure 5). Such ring-shaped aggregations are readily produced by weak acids of any kind.

FIGURE 5. Path of the single *Paramecium* in a ring about an acid region. (After Jennings 1906)

The entrance to the acid region results merely from the natural lively roving movements of the animals. They do not "orient" and swim directly toward the acid area, but enter it in their roving course, and then remain.

Thus the single *Paramecium* cell is enveloped in a faintly acid aura. When a number of individuals come close together, their auras blend till a large faintly acid area is produced, in which a dense aggregation is formed.

Some other infusoria form aggregations in the same manner. *Colpidium colpoda*, *Cyclidium glaucoma* and *Chilomonas paramecium* collect in acid areas and form spontaneous aggregations, just as do species of *Paramecium*. When individuals of any of the above-mentioned species are mingled with those of *Paramecia*, all aggregate together in the same region.

But it is notable that certain other species of Protozoa belonging to the same group as *Paramecium* (the ciliate infusoria) form spontaneous aggregations that are not due to acid. *Oxytricha aeruginosa* and *Loxocephalus granulatus* collect in the same way as does *Paramecium*, but the areas in which they gather are not acid in reaction, and animals of these species do not aggregate in weakly acid solutions. If a mixture of individuals of *Paramecium* and of one of these species (*Oxytricha*, for example) is placed on a glass plate and covered as before described, both species form spontaneous aggregations, but the two aggregations are separate. Individuals of either species pass freely across the area of aggregation of the other species, not reacting at the boundary or remaining within the area.

Thus *Oxytricha* and *Loxocephalus* give off certain substances that form an aura about them, just as do *Paramecium*, *Colpidium*, *Cyclidium* and *Chilomonas*, but the substances are different in the two cases. The nature of the non-acid substances has not been investigated. It appears probable that a variety of such substance may be discovered when the natural history of the different species of infusoria is more fully examined.

2. There is evidence that some of the free-living Protozoa give off into the water substances that promote the reproductive processes of other individuals of the species. The picture here is far from clear, the phenomena being much less marked than in the class of cases just considered.

The fundamental observation is this: If several individuals are present in a small space, in some species each individual multiplies more rapidly than do single individuals kept separately. It appears, therefore, that the individuals in such cases probably secrete materials that pass into the water and stimulate other individuals to reproduce. The phenomenon was described for certain ciliate infusoria by Robertson in 1921; he called it the allelocatalytic reaction. Investigations have been carried out on many different species since Robertson's work, some seeming to confirm his views, others to contravene them.

In most cultures of infusoria the nutritional conditions are extremely complex, owing to the presence of bacteria, on which many species feed. This makes interpretation of the observed phenomena difficult. Investigators working with bacteria-free cultures have in a few cases confirmed the greater rate of reproduction when a number of individuals are present (Mast and Pace, 1938, in *Chilomonas*; Kidder, 1941, in *Tetrahymena*). In *Chilomonas* a substance is seemingly produced by the organisms, which in low concentrations increases the rate of reproduction, but decreases it when more concentrated.

In many cases the presence of excretory products in the water seemingly decreases the rate of multiplication. Yet cases are known in which the addition to the nutritive medium of old culture fluid, presumably containing excretory products, results in increase of reproduction. These and similar facts greatly complicate the situation as to allelocatalytic action.

Knowledge on this matter is thus in an unsatisfactory condition. The phenomena, if real, are very inconspicuous as compared with those shown in the aggregations of infusoria described in the previous section. Summaries of the data on the matter, and discussions of their significance will be found in the two chapters contributed respectively by R. P. Hall and O. W. Richards to the book "Protozoa in Biological Research" (1941), edited by Calkins and Summers.

3. Very conspicuous again are the phenomena shown in the sexual aggregations of infusoria. The organisms produce materials which cause individuals of different sex type to cling together in groups, and finally to unite in copulation or conjugation. Many remarkable phenomena result. The basic phenomena are as follows:

In some species of Protozoa there are two sex types, as there are two sexes in higher animals and plants. In other species or varieties there are four, eight, or even a larger number of sex types. When all the individuals in a region belong to the same sex type, the individuals remain scattered, swimming about freely (as in the upper left photograph, Figure 7). But when individuals of two different sex types (of the same species or variety) are mingled, the individuals cling together, forming clots or masses containing many individuals. Photographs of such clots, in comparison with the scattered individuals of single sex types are shown in Figures 6 and 7. The former shows the phenomena in certain minute flagellate infusoria; Figure 7 shows them in the large ciliate infusoria. In superficial features at least the phenomena resemble the agglutination of bacteria or of blood cells.

Details of the clotting may be illustrated from *Paramecium bursaria* (Figure 7), in which the cells are large enough so that the behavior of individuals can be ob-

FIGURE 6. Clots formed by *Chlamydomonas eugametos*. At the left is shown the condition when individuals of but one sex type are present; they remain scattered. At the right, two sex types are present; by their adhesion they have formed large groups or clots. (After Moewus 1938)

served. The cell bodies are covered with fine cilia, by the motion of which the organisms swim about in the water.

FIGURE 7. Photographs of the mating behavior in *Paramaecium bursaria*. Upper left, individuals of but one mating type; they remain scattered. Upper right, mixture of two mating types, six minutes after the two were mingled. The individuals have adhered to form large clots. Lower left, mixture of two sex types about five hours later. The large clots have broken down into smaller ones, chains, and pairs. Lower right, mixture of two sex types 24 hours later. Most of the individuals are in pairs. (After Jennings 1939)

In this species there are in some varieties four different sex types, in other varieties eight. The individuals of the different sex types do not obviously differ in form or structure, but behave differently in the sexual reactions. When many individuals of two or more different sex types are placed together in a small amount of water, they at first continue their usual roving movements. These movements bring some of the individuals into accidental contact. If the two individuals that touch belong to different sex types, they stick together as if their bodies were covered with a strong adhesive material. Any parts of the cell body that thus come into contact adhere. The two individuals may thus adhere by their aboral or oral surfaces, by their rear ends or anterior ends, or in any other way. Thereupon they begin to move in an irregular way consequent upon the divergent action of the cilia in the two individuals. A third and fourth individual may become attached to the two; all flounder about irregularly. The groups continue to grow by the attachment of other individuals, till large clots are formed, such as are seen in Figure 7. Figure 8 shows a number of observed cases of irregular adhesions in early stages of the phenomena when

the individuals are few. Where two individuals adhere, often one of them drags the other backward or sidewise.

At the beginning it is the cilia that stick together. The cilia that are in contact on the two individuals are immobilized, while the free cilia continue to vibrate. Later the bodies come into contact by their surfaces, the union finally becoming intimate. In the large clots the individuals are in irregular contact by any parts of the body. It is always individuals of two different sex types that adhere; individuals of the same sex type do not.

FIGURE 8. *Paramaecium bursaria*. Irregular adhesion of individuals, in the early stages of the clotting that occurs when members of different sex types are mingled together. The arrows present in certain figures show the divergent directions in which the cilia tend to carry the different individuals. (After Jennings 1939)

In the entire behavior, in the case of ciliate infusoria such as *Paramaecium*, it is evident that the coming together of the individuals is the accidental result of their natural roving movements. They do not orient at a distance and swim toward each other, or toward a group already formed. In some of the minute flagellate infusoria, on the other hand, there is said to be orientation at a distance, one cell swimming directly toward another or toward an aggregation already formed.

The large masses containing many adhering individuals usually remain united for about a half hour, then begin to break up into smaller masses. This slow break-

ing up is hastened by the approach of evening. By the disintegration of the large groups smaller groups are formed, and the process continues until only pairs of individuals remain in contact. These become attached by their oral surfaces, partly fuse, and remain united for many hours. During this period of union they exchange halves of their nuclei; that is, they fertilize one another. Then they separate, and each multiplies by fission. Such a sexual union, in which the two cells finally separate and each continues to multiply, is known as conjugation. The lower right photograph in Figure 7 shows the conditions after the clots have disintegrated and most of the organisms are in conjugating pairs.

In the Flagellates the phenomena are in the main similar to those in the Ciliata, but there are certain important differences. The flagellates are much more minute than the ciliates, so that the behavior of the individuals is not readily observable. But upon mixture of two different sex types of a species, large clots are formed by the adhesion of many individuals, just as occurs in the ciliates. This is shown in Figure 6. The large clots in the course of time break up into smaller clusters, and this continues (as in the ciliates) until only pairs of two individuals remain united. In the flagellates the two cells of the pair unite completely to form a single cell (the zygote). Such complete sexual union into one cell is known as copulation. The single cell or zygote later divides, producing many cells.

The phenomena above described suggest that in the flagellate and ciliate infusoria the cells of different sex types produce characteristic substances ("sex stuffs"), and that these sex stuffs cause the adhesion between cells of diverse sex types. The existence of such sex stuffs was demonstrated for the flagellates by Moewus, in 1933. In the species *Chlamydomonas eugametos*, Moewus removed the cells from dense cultures of the organisms, by centrifuging, or by filtration, leaving only the fluid. When this was done with cultures that were throughout of one sex type, and with the fluid so obtained individuals of the other sex type were treated, these individuals were caused to clot, just as occurs when individuals of the other sex type are added. In such clots, however, there is no final complete union of the cells, such as occurs when the two sets of cells belong to different sex types.

The sex stuffs have other effects. In a culture of *Chlamydomonas* of which all cells are of the same sex type, there is a certain period of development in which the cells are immobile and incapable of sexual union. If while in this condition they are treated with a filtrate from active functional cells that are of their own sex type (and that are capable of sexual union), this filtrate causes them to become likewise active and capable of sexual union.

Since the adhesion and aggregation of the organisms are thus shown to be due to their production of sex stuffs, the nature and properties of the sex stuffs are partly discoverable by the phenomena to which they give rise. These phenomena are varied and complex. Some of the chief features of the nature and action of the sex stuffs are the following:

(a) The adhesion and clotting that result from the presence of the sex stuffs is a reciprocal reaction between two different stuffs. In the clots of *Paramecium* the animals stick together as if covered with glue. But this is not due to a general adhesiveness of the cell bodies. The *paramecia* do not adhere indiscriminately to objects with which they come in contact. They do not adhere to inanimate objects, nor to individuals of their own sex type, nor to immature individuals, nor to individuals of another variety or species. Two different sex types or sex stuffs (belonging to the same variety or species) must be present in mature condition, for adhesion to occur.

(b) The sex stuffs exist as many diverse kinds. The number of differently acting sex stuffs in any species is necessarily the same as the number of differently acting sex types. In *Paramecium bursaria*, therefore, there are at least sixteen different sex stuffs. In Variety I of this species there are four sex types each differ-

ing in its adhesiveness from the other three. In Variety II eight sex types exist, each reacting differently from any of the other seven, or from any of the four of Variety I. In Variety III there are again four different sex types, none of them adhering to any of the sex types of Variety I or Variety II. Thus each of the sixteen different sex types in the three varieties of *Paramecium bursaria* shows different phenomena of adhesion from any of the other fifteen. In *Paramecium aurelia* three varieties are known, each with two sex types, so that the number of known different sex types is six. In the flagellate *Chlamydomonas* two diverse groups of sex types are known. In one of the groups there are six diverse interacting sex types, in the other group eight. In certain other flagellates and ciliates numbers of diverse sex types are known.

(c) The nature and properties of the sex stuffs have been directly studied mainly by Moewus (1938, 1940) in the flagellates. In *Chlamydomonas* there are in any variety two sex types, which Moewus calls male and female: we may follow him in these designations. In *Chlamydomonas eugametos* there is an inactive stage, from which the organisms are roused to activity by light. When first aroused to activity they are not capable of sexual union. But if subjected to light (blue or violet rays) for fifteen to twenty minutes, they become so; at this time active sex stuffs are presumably present. To make them capable of sexual union, male cells require longer subjection to light than do female cells.

In the stage when the cells are active (but still not capable of sexual union) the cells may be filtered out of the fluid in which they are found. In this way is procured a filtrate that is free from cells. Such a filtrate may be prepared from a culture of either male or female cells.

The filtrate thus obtained is inactive at first. But if subjected to light (blue) it produces the active sex stuffs (which induce adhesion and clotting as above described). When subjected continuously to light it first (after about twenty minutes) produces the female sex stuff. If the action of the light is continued (to about thirty minutes) the filtrate produces the male sex stuffs. The two sex stuffs thus produced from the filtrate have the characteristic effects of sex stuffs above described. Subjected for a still longer time to light the filtrate becomes inactive. The changes just described occur in the same way whether the filtrate is prepared from male or from female cells.

Thus four stages may be distinguished in the material of the filtrates: (1) a preparatory stage, inactive: (2) the female sex stuff: (3) the male sex stuff: (4) a final inactive condition.

If a filtrate is procured from active functional female cells (female sex stuff), this when subjected to blue light transforms into the male sex stuff. But the female stuff cannot be obtained from the male sex stuff.

By making mixtures of the preparatory stuff (1) and the inactive end stuff (4), the two sex stuffs can be produced. The female sex stuff is produced by mixing three parts of the preparatory stuff (1) with one part of the end stuff (4). The male sex stuff is derived by mixing one part of the preparatory stuff (1) with three parts of the end stuff (4).

It is clear, therefore, that the male and female sex stuffs (as well as the preparatory and end stuffs) are related substances: light transforms one into the other.

In the course of the experiments above described, Moewus tried the effects of various organic compounds, to see if similar phenomena could be observed. From the fact that the stuffs are transformed by blue and violet light, he was led to suspect that they are probably related to yellow or orange-yellow organic compounds. He was therefore led to experiment with such compounds (carotinoids) derived from the carrot, *Daucus carota*. He made watery extracts from the carrot, and found that one of these had an action similar to that of the female sex stuff. Moreover, when it had stood a while in the light, it acted like the male sex stuff.

This led Moewus to experiment with a large number of known carotinoids. Most were ineffective. But two of them acted like the sex stuffs. One of these, *cis*-crocetin dimethylester, has the properties of the preparatory stuff (1), while the related *trans*-crocetin dimethylester has the properties of the final inactive stuff (4). Mixtures of three parts of the *cis* compound with one part of the *trans* compound have the properties of the female sex stuff, while one part of the *cis* material with three parts of the *trans* material yields the properties of the male sex stuff.

It appears, therefore, that the male and female sex stuffs of *Chlamydomonas eugametos* are closely related materials belonging to the carotinoid group of compounds: they are presumably identical with mixtures of the *cis* and *trans* forms of crocetin dimethylester.

This work was extended by Moewus to include the sex stuffs in certain other varieties or species of *Chlamydomonas*, the sex types of which interact in accordance with certain rules. In these varieties eight different sex stuffs may be distinguished. They turn out to be different percentage combinations of the *cis* and *trans* forms of crocetin dimethylester. We may take from Sonneborn (1941, p. 677) a table showing the percentages of the *cis* and *trans* materials in these eight sex stuffs (designated in the table by the letters G to O).

| | G | H | I | K | L | M | N | O |
|-------------------------|----|----|----|----|----|----|----|----|
| Percentage <i>cis</i> | 95 | 85 | 75 | 65 | 35 | 25 | 15 | 5 |
| Percentage <i>trans</i> | 5 | 15 | 25 | 35 | 65 | 75 | 85 | 95 |

In this series of sex types, individuals or varieties having the same sex stuff do not unite, nor do those differing in the percentage combination by less than 20 per cent. But any individual or variety unites with others that differ from it by 20 per cent or more in its combination of *cis* and *trans* substances.

Moewus calculates that the latter are effective in producing copulation in a dilution of one part in 33 billion.

No such investigation has been made of the chemical nature and physical properties of the sex stuffs in the ciliates. But the similarity of the phenomena in this group to those in the Flagellata strongly suggests that they are brought about in a similar manner.

(d) Certain peculiarities of the phenomena in the ciliates suggest a possible difference in the nature of the sex stuffs in the two cases. In the flagellates the sex stuffs are water-soluble materials (Moewus, 1938, p. 765), which are obtainable free from the organisms by filtering or centrifuging. They are thus present in solution in the culture medium. With this agrees the method of reaction of individuals of one sex type to those of the other sex type, as described by Pascher (1931) in *Chlamydomonas*. The active cells of one sex type orient about a quiet cell of the other sex type and from a distance swim directly toward it. Such reaction at a distance and orientation requires that the effective substance shall be dissolved in the water surrounding the cells. But in the ciliates the phenomena suggest that the adhesion and aggregation are surface phenomena, the sex stuffs being active only at the surface of the cells, and not in solution in the surrounding water. For in these organisms there is no reaction at a distance; the cells of one sex type do not orient and swim from a distance toward a cell of another sex type. The adhesion occurs only when the animals come in contact through their roving movements. These natural roving movements occur equally when cells of only one sex type are present. Such cells come in contact as frequently as do cells of different sex type, but when the cells are of the same sex type they do not adhere. It is desirable that investigation be directed upon the question whether in the ciliates the sex stuffs are dissolved in the surrounding fluid, or occur only on the cell surface.

(e) In the life history of the ciliates there is a period of immaturity, during which the organisms do not produce sex stuffs, and there is no adhesion, aggregation

or conjugation. This period of immaturity lasts for many cell generations. An individual cell that has just completed conjugation divides into many cells by repeated fissions, producing a large population known as a clone. All members of the clone are for a long time immature, showing no sexual reactions of any sort. In *Paramecium bursaria* immaturity continues for a period of from one to several months. During this time fission takes place at the rate of about one a day, so that millions of immature individuals are produced. Then comes a period during which maturity slowly develops. Now the cells presumably produce the sex stuffs, since they show the selective adhesion, aggregation and conjugation above described. The period of immaturity is one in which the cells neither produce sex stuffs, nor react to sex stuffs from other cells. For if to a clone of immature individuals we add a clone of highly reactive mature individuals of different sex type, there is no adhesion, clotting or conjugation between the two.

(f) In some of the ciliates (if not all) there is a daily periodicity in the occurrence of sex reactions, and therefore in the production of sex stuffs. In most varieties of *Paramecium bursaria* and *Paramecium aurelia* adhesion and clotting occur only at certain periods of the day. In Varieties I and II of the former the adhesion and other sex phenomena normally occur only during the daylight, from about nine A.M. to five P.M. In Variety 2 of *Paramecium aurelia* they occur only at night, from about six P.M. to seven A.M. In Variety 3 of the same species they occur only from about one A.M. to one P.M. In some other varieties there appears to be no periodicity; adhesion, aggregation and conjugation occur whenever different sex types are mixed. This is the case in Variety I of *Paramecium aurelia* and Variety III of *Paramecium bursaria*.

The periodicity in the sex reactions, and thus in the production of sex stuffs is due in the long run to the alternation of day and night. Yet the phenomena are not immediate direct effects of light and darkness. If the cultures are kept in continuous light or continuous darkness, the usual periodicity persists for some days. In this way *Paramecium bursaria* (Variety I or II), which normally reacts only in daylight, may be caused to react at the usual time though in total darkness. The periodicity of day and night has become a periodicity of organic processes, which become partly independent of the external periodicity. Yet if the periodicity of light and darkness is totally suspended for a long time, the periodicity of the sexual reactions is in time broken up and disappears. Sonneborn (1938) shows that in *Paramecium aurelia* (Variety 3) after five days of continuous light the sexual reactions are entirely lost, while after five days of continuous darkness the adhesion and clotting will occur at any time the two sex types are mixed.

(g) When the members of one clone have become mature, in *Paramecium bursaria* all are found to belong to the same sex type. As the clone continues to multiply, all the descendants by ordinary fission continue to remain of the same sex type, so that in ordinary fission the sex type is strictly inherited. This is the rule also in *Paramecium aurelia*, and seemingly in most species.

Even in the immature condition there are inherited differences between clones, corresponding to the later differences in sex type. For all the members of a given immature clone later develop the same sex type, and hence must produce the same sex stuff; whereas in another clone a different sex type (and sex stuff) is produced.

(h) But there occur in a clone at long intervals nuclear processes of special type, which result in the differentiation of the members of the single clone into two different sex types, producing different sex stuffs. Such phenomena, varying in different species, are known to occur both in the flagellates and the ciliates. They need not be more fully described here.

(i) At sexual union (conjugation in the ciliates, copulation in the flagellates), followed by fission, inheritance of the sex types occurs in accordance with varied and complex rules.

For details as to the rules of inheritance, and in general as to the biological rôles of the sex types, the chapters contributed by Sonneborn (1941) and Jennings (1941) to the volume "Protozoa in Biological Research" (edited by Calkins and Summers) may be consulted. These chapters contain extensive lists of references to the papers setting forth the original investigations on these matters.

The Primary Physicochemical Basis of Organic Evolution

C. R. PLUNKETT

Definitions are made by man, and ignored by nature. It is a common experience in all fields of science that while increasing knowledge, up to a certain point, tends to bring out sharp distinctions between things formerly confused, beyond that point further advances often tend to break down these sharp distinctions. The distinction between living and lifeless things seems to be a case of this kind. This distinction was built up slowly, over a long period, with the gradual decline of primitive "animism," the recognition of the features common to plants and animals, the discovery of microorganisms, the step-by-step disproof of "spontaneous generation," etc. This phase reached its culmination during the nineteenth century, with the establishment of an "absolute" distinction between living and non-living things, embodied in various epigrammatic definitions of "life," and elevated to the status of a metaphysical categorical difference beyond the scope of scientific elucidation.

But this laboriously built boundary wall had scarcely been completed, before it began to show cracks. The theory of evolution itself, though on the one hand it unified the biological sciences, on the other hand tended to raise anew, and in a quite different aspect, the question of the possible natural origin of living from lifeless things. So also the cell theory, while aiding in the unification of biology, tended to encourage the further pursuit of "life," tracked down from the whole organism to the cell, into the still smaller components of the cell. Later this pursuit was greatly advanced by the gene theory, which has carried it down, through the gene, close to the chemical molecule.

Meanwhile the boundary wall was also being undermined from the other side by the artificial synthesis of ever-increasingly complex "organic" compounds, by the isolation, crystallization, analysis, and synthesis of the "mysterious" enzymes, vitamins, and hormones, by the demonstration of the conservation of energy in the living body, and later the step-by-step disproof of the alleged "exception" of living things to the second law of thermodynamics. Also from the physicochemical side, the advance of colloid chemistry and the theory of catalysis pushed upward, through the chemical molecule and the colloidal micelle, toward a junction with cytology and genetics pushing downward through the chromosome and the gene. Then, from an unforeseen direction, appeared a new opening—the discovery of the filtrable viruses—which went far toward completing the breach in this boundary wall: so far, indeed, that there is no agreement at all, even among those who would still maintain this wall, as to which side of it the viruses belong.

More recent advances in several fields of biology and chemistry—virus study, cytochemistry and gene physiology, the chemistry and physiology of enzymes and nucleoproteins, the general theory of catalysis, etc.¹—have still further reduced the sharpness of the distinction between living and lifeless things, and leave little further excuse for regarding this difference as "absolute," or treating it as a metaphysical question outside the scope of scientific investigation. Rather must it be treated as a special bio-physico-chemical problem, to be elucidated by the continued development of experimental methods and the correlation of results in the several pertinent fields of investigation.

The characteristic properties which are supposed to distinguish living from non-living things are variously enumerated, defined, and emphasized by different biologists. The more generally cited of these characteristics include: the chemical composition of living bodies, characterized by the presence of complex carbon compounds, especially proteins, and particularly of specific optically active stereoisomers (in contrast to the racemic mixtures generally produced by artificial syntheses); the physicochemical structure of living matter, a complex, unstable, polyphase colloidal system, to which the rather indefinite term "protoplasm" is applied; over and above this general ultramicroscopic structure, the specific, highly differentiated, microscopic and macroscopic structure of cells and multicellular organisms (often designated as "organization"); metabolism, in its broadest sense including all the chemical reactions occurring in living organisms; liberation of energy in various forms, including movements, heat, bioelectric currents, etc.; responsiveness (also called "irritability" or "reactivity"), involving, in some of the higher organisms at least, subjective ("mental") aspects correlated with its objective manifestations; growth (often specified as being "by intussusception," which is merely a consequence of the heterogeneous, largely liquid, structure of protoplasm) and reproduction, involving the phenomena of heredity and variation. It is notoriously difficult, if not impossible, to define any of these properties in such a way as to distinguish them sharply from comparable properties displayed—though usually in simpler and more generalized form—by at least some non-living systems. Moreover, these properties are obviously not independent of, or sharply separable from, each other. And as to what particular property, or combination of properties, is most essentially distinctive or diagnostic of "life," there is the widest possible divergence of opinions among workers in the various fields of biology and biochemistry.

Once we frankly recognize the difference between living and lifeless things as relative, rather than absolute, we may approach this question in a somewhat different way: we may regard the complex of phenomena which we call "life" as characterized not so much by any unique special property, or properties, as by certain general features displayed in especially high degree by many of the properties of those bodies recognized, by general consent, as "living." These general features—which are entirely relative, and all closely interrelated—may be designated as *complexity*

specificity, *diversity*, and *adaptation* (though they might be equally well named, divided, and combined in many other ways).

It is fairly generally recognized that many, if not all, of the characteristic properties of living organisms, whether chemical or physical, structural or functional, are distinguished from comparable properties of some non-living systems, not by any strictly definable qualitative differences, but rather by their higher degree of complexity. The composition and structure, the chemical reactions and physical activities, the responses and the growth of organisms are all much more complex than those of any non-living bodies. Even so complex and apparently peculiar a phenomenon as reproduction may be resolved into component processes (division, specific growth, etc.) each of which has simpler counterparts in some non-living systems.

The high degree of specificity so characteristic of many properties of organisms—their chemical components and reactions, their structures, responses, growth, etc.—is obviously correlated with their complexity. Simpler things, *e.g.*, inorganic chemical substances, may be just as specific, or even more so, but their specificity is likely to be less impressive because it does not involve such complex qualities and activities. While some of the specificity of organisms is individual, the greater part of it is group specificity (species-specificity, etc.) common to a group of individuals related by descent, *i.e.*, it is transmissible, or hereditary, specificity.

Diversity is, on the one hand, a correlative of specificity (for the specificity of one thing implies its diversity from other things, and conversely); but on the other hand, considered genetically rather than statically, it implies a limitation of hereditary specificity: for any diversity among individuals related by descent indicates that this specificity is not absolute, but more or less modifiable. Some, though not all, of the diversity originating by modification of transmitted specificity is itself specifically transmitted in turn. This continual modification and diversification of hereditary specificity by new heritable diversity results in the complex gradation of resemblances and differences among organisms, which involves all their characteristics more or less correlatively (*e.g.*, morphological similarities are correlated with similarities of specific chemical components, etc.).

The word "adaptation" has fallen somewhat into disrepute among many biologists because it has sometimes been used with teleological or vitalistic implications; but it is a perfectly good word to designate one of the most striking and universal features of practically all the characteristics of living organisms. In its most general sense, adaptation means merely "fitness to exist" in a given environment, which implies simply a certain degree of stability within a certain range of conditions. In this general sense, any organism is less "adapted" than many inorganic bodies, which are more stable and continue to exist much longer. It is, evidently, the complexity, the specificity, and the diversity of the adaptation of an organism which make it so remarkable. Adaptation, in any individual organism, has two aspects: first, its inborn, inherited, structural and functional "adaptedness"; and second, its "adaptability," or ability to change individually to meet changing conditions. It is sometimes supposed that this second aspect, individual "adaptability," is primary—an aboriginal, essential attribute of "life"—giving rise, somehow, to all the diverse specific hereditary adaptations of organisms (*e.g.*, Lamarck's theory of the inheritance of the effects of use and disuse, etc., in which the original effects, in the individual, are taken for granted without explanation). Actually, the relation between these two aspects of adaptation is just the opposite: individual "adaptability" is not the antecedent but a consequence—indeed, but one manifestation—of specific hereditary "adaptedness": an organism responds in a way advantageous to itself (*i.e.*, "adapts" itself) to a particular change of conditions only because, and if, it is already provided with some inherited special adaptive mechanism whose function it is to respond in just that particular way to that particular change. In many cases, of

course, one special adaptive mechanism may cover a number of contingencies which are not exactly alike but have some elements in common; but, in general, an organism does not respond "usefully" to a situation which is entirely new, or extremely unusual, in the history of its race. The complexity, specificity, and diversity of the adaptations of organisms are practically coextensive with the total complexity, specificity, and diversity of all their properties; indeed, there is relatively little of anything in an organism which is not adaptive. This situation has a completely adequate causal explanation in the theory of natural selection, which rests solely on the universal characteristics of biotic reproduction: multiplication, heredity, and variation.

Multiplication, heredity, and variation, though traditionally treated as separate "factors" in organic evolution, are really only conceptually separable aspects of a single process. For "heredity" implies *specific multiplication*, whereas "variation" implies that this specificity is somewhat *modifiable*: we may, therefore, characterize biotic reproduction as "modifiably specific multiplication." However, not all variation (*i.e.*, all diversity among organisms related by descent) is significant for evolution, but only *heritable* variation, *i.e.*, such variation as, originating by modification of self-reproducing specificity, is itself specifically self-reproducing thereafter (subject, of course, to further modification of the same kind). This kind of variation is now called "mutation" (disregarding disputed questions of technical definition, occasioned by various complications in the higher organisms). We may say, therefore, that the primary basis of organic evolution is *mutably specific multiplication*.

If the properties of living things differ from those of non-living things only in degree (of complexity, etc.) we might expect to find in some non-living systems properties comparable in some degree to mutably specific multiplication, though presumably in simpler and more generalized form. In the field of *catalysis* we find many examples of extreme specificity and also of modifiable specificity.² We also find a form of catalysis involving self-increase, or multiplication: namely, *autocatalysis*. By autocatalysis, in general, is meant catalysis of a reaction by one of its own products; the substance thus catalyzing its own production is called an *autocatalyst*. Autocatalysis, in this general sense, is no different, in regard to the chemical mechanisms involved, from heterocatalysis (*i.e.*, non-autocatalytic catalysis); it just happens (so to speak) that some substances catalyze reactions of which they themselves are products. Thus, for instance, the hydrolysis of an ester (in originally neutral solution) is autocatalyzed by the free acids produced; but this is no different, in its chemical mechanism, from the heterocatalysis of this reaction and other hydrolytic reactions by any acid. Again, the oxidations of many metals, and of various organic substances, are autocatalyzed by some of their oxidation product (peroxides) which act as oxygen "carriers"; this is the same mechanism by which in many oxidative reactions, "foreign" peroxides act as heterocatalysts. While the rate of a heterocatalytic reaction is usually either continuously decreasing or constant, depending on the relative concentrations or effective surface areas of catalysts and reactants and other conditions of the system, the rate of an autocatalytic reaction *under the simplest conditions* (*i.e.*, in a completely homogeneous closed system) will increase continuously for some time, because of the increasing concentration of the autocatalyst; but under other conditions, *e.g.*, insolubility of the autocatalyst or some of the reactants, continuous removal of the autocatalyst from the reaction system, etc., the rate of an autocatalytic reaction may also be constant or even decrease continuously from the beginning; the form of the reaction velocity curve is therefore neither a sufficient nor a necessary criterion of an autocatalytic reaction especially in a complex heterogeneous system.

Catalyst *specificity* is, of course, a relative matter, and there are various degrees of specificity in different cases, in general chemistry as well as in biochemistry. The specificity of a catalyst consists in its effectiveness in catalyzing selectively or

particular reaction (involving certain particular reactants and yielding certain particular products), as measured by the rate of this particular reaction *relative* to the rates of other (simultaneous or possible) "competing" reactions (whether involving some different reactants or yielding different products from the same reactants) when catalyzed by this particular catalyst, *as compared with* the rate of this particular reaction relative to those of the "competing" reactions when catalyzed by any other catalyst (or uncatalyzed). In the case of autocatalysis, a highly specific autocatalyst would be one which catalyzes very selectively a particular reaction, one of whose products is *identical* with the autocatalyst (not merely any substance in the same general class), which would otherwise occur much more slowly, if at all, whether uncatalyzed or catalyzed by any other catalyst. Most of the autocatalytic reactions well known in general chemistry are not very specific: *e.g.*, the acid hydrolysis of esters, the "autooxidation" of metals and of various organic substances, etc. These reactions may be catalyzed by other catalysts (*i.e.*, heterocatalysts) just as effectively as by their own autocatalysts, or even more so; and the autocatalysts are merely general catalysts for all reactions of a certain type, of which the autocatalytic reaction happens to be one. Although there are many well known and extensively investigated cases of highly specific *heterocatalysis* in general chemistry, I have been unable to find any well established cases (not involving biocatalysts) of very specific autocatalysis of a strictly "chemical" nature. On the rather ill-defined borderline between "chemical" and "physical" processes, however, there is a very extensive and well known class of phenomena which are highly specific and comparable in some respects, at least, to autocatalysis: namely, *crystallization*.⁸

A crystal accelerates, or even initiates, very selectively, the formation from certain particular substances of more material identical (in most cases) with itself, which would otherwise occur much more slowly, if at all. Often it is difficult, in some cases almost impossible, to initiate crystallization except by "inoculation" with a crystal of the particular substance concerned; but even when crystallization starts spontaneously (*i.e.*, without "inoculation") the first-formed, ultramicroscopic crystals must greatly accelerate the process of crystallization at their surfaces; otherwise, we should never get visible (even microscopic) crystals at all, but only apparently "amorphous" precipitates. The degree of *chemical* specificity of crystal growth varies in different cases (*e.g.*, the cases of isomorphous substances), though in most cases it is highly specific; but the *crystal structure* is always highly specific.

Crystals of different (non-isomorphous) substances may grow simultaneously in the same solution, each crystal selecting and combining the particular kinds of molecules or ions of which it is itself composed. In the case of non-electrolytes (such as many organic compounds), this consists merely in selectively adsorbing already existing molecules of its own kind and arranging them in a definite pattern, or "space lattice"; but in the case of strong electrolytes (*e.g.*, salts), it involves taking up ions of two or more different kinds, in definite proportions, and arranging them in definite spatial relations to each other. Just such selective combination, definite orientation, and intimate juxtaposition of specific molecules or ions are indispensable prerequisites of chemical synthesis, and especially characteristic of surface catalysis; but in crystallization these preliminaries are not followed by "chemical" combination, in the usual sense of the word, that is, the formation of new primary co-valence bonds, such as are especially (though not exclusively) characteristic of organic compounds (*e.g.*, such bonds as C-C, C-N, C-O-C, etc.). For this reason, crystallization is not usually regarded as a chemical process, and hence we do not speak of it as "catalysis."

In contrast to such strictly "chemical" bonds, which are both strong and specific, the forces binding the components of a crystal are of two kinds: the strong but non-specific electrostatic attractions between oppositely charged ions (in electro-

lytes); and the specific but usually relatively weak "secondary valence" forces, or residual external electric fields of molecules. The fact that practically all substances may crystallize, under proper conditions, indicates that there is always some specific attraction between molecules of the same kind, though its strength varies widely in different substances.

The same specific "iso-molecular" cohesive forces are undoubtedly involved also in the formation of other kinds of iso-molecular aggregates, such as colloidal particles, fibers, and gels, which are especially characteristic of many complex biochemical substances, *e.g.*, proteins and polysaccharides. Specific intermolecular attractions also exist between molecules of different kinds, but the strength of these "hetero-molecular" forces varies even more widely in different cases: they may be much weaker than iso-molecular cohesion, or apparently even non-existent, in many cases (*e.g.*, between hydrocarbons and water), while at the other extreme (in so-called "molecular compounds") their strength approaches that of primary chemical bonds. In specific heterocatalysis the specific attractive forces between catalyst and reactants are strong enough to distort the molecular electric fields of the reactants sufficiently to disrupt (or greatly weaken) their primary chemical bonds and thus permit the formation of new bonds: this constitutes chemical "synthesis" or "decomposition," according to the relative sizes of the original and the resultant molecules. (Of course the distinction between primary and secondary valences is not entirely sharp, and therefore the question whether the "intermediate compounds" of catalyst and reactants are "adsorption compounds" or truly "chemical" compounds may often be one of somewhat arbitrary definition.)

From the foregoing considerations, it would appear that *specific autocatalysis* must involve some sort of combination of the kind of forces involved in specific iso-molecular aggregation (crystallization, etc.) and the kind involved in specific catalysis, especially surface catalysis, which may include catalysis at the surfaces of relatively large discrete molecules; in other words, specifically iso-molecular attractive forces with some of the special characteristics of the hetero-molecular forces between catalyst and reactants which facilitate the disruption or redistribution of primary co-valence bonds, resulting in chemical recombinations between the reactant molecules.⁴ Since these two kinds of forces (*viz.*, iso-molecular and catalytic) are both, separately, very common, and are moreover fundamentally similar, both being manifestations of residual external electric fields of molecules, we might expect their combination to be not extremely unusual; but the fact is that highly specific *autocatalysis* is apparently still unknown in indisputably non-living matter. This would seem to suggest that some very special feature of molecular composition or structure may be necessary for a specifically autocatalytic substance; *e.g.*, the presence of some particular atomic grouping in the molecule, or perhaps some peculiar feature of the structure of the molecule as a whole. It should be noted, however, that certain special conditions of the milieu may be equally necessary for the autocatalytic activity of such a substance, especially if the autocatalytic reaction is one by which the autocatalyst is synthesized from simpler substances. The conditions must be such as to permit this reaction to proceed predominantly in the synthetic direction; for if the reverse reaction predominated it would result in the self-accelerated decomposition of the autocatalyst and eventually (unless an equilibrium were reached) its complete loss.

Predominance of the synthetic reaction requires either that all the component substances, from which the autocatalyst synthesizes itself, be maintained in sufficient concentration, in the immediate milieu, to force the reaction in the synthetic direction (by "mass action"), or else that the synthetic reaction be practically irreversible under the conditions of the system. The latter alternative implies that some product of the reaction (either the autocatalyst itself or some "by-product" of its synthesis) be continuously removed from the phase in which the reaction occurs; *e.g.*, if the

synthesis involves combination of two or more molecules with elimination of the elements of water (so that the reverse reaction is hydrolytic), the autocatalytic synthesis must either proceed in a non-aqueous phase, from which the water is continuously removed by some means (chemical or physical) as fast as it is formed, or else the autocatalyst itself must escape continuously, as it is formed, from the aqueous phase, *e.g.*, by precipitation or diffusion. In a heterocatalytic reaction, the reaction can be kept going in the desired direction by the continuous removal of the products, as formed, from contact with the catalyst, but this is not possible in an autocatalytic reaction, for the autocatalyst cannot be removed from contact with *itself*. In addition, other special conditions of the reaction system (temperature, pH, other ionic activities, oxidation-reduction potential, etc.) will presumably be necessary for the autocatalytic reaction, as in other catalytic processes. The more complex the autocatalytic substance and the reaction by which it synthesizes itself may be, the more complexly and specifically "adapted" to this reaction, presumably, must be its milieu. (In this connection it is significant that all the synthetic reactions in a living organism cease, and decomposition proceeds irreversibly, as soon as the organism is "dead," *i.e.*, upon the failure of any of the complex of conditions necessary for the synthetic processes.)

Modification of catalyst specificity (however effected) consists in increasing or decreasing the effectiveness of the catalyst on one particular reaction, while leaving unchanged, or changing to a different extent or in the opposite direction, its effectiveness on other "competing" reactions: thus the modification may increase or decrease the original specificity of the catalyst or alter it qualitatively (*i.e.*, render the catalyst specific for a different reaction from the one for which it was originally specific). Many cases of such catalyst modification are well known in general chemistry. Changes of specificity of biocatalysts also can be effected artificially; and it is not improbable that such modifications may also occur naturally, in the living organism, and may play important roles in various biological processes.² Such modification, when a *heterocatalyst* is concerned, does not constitute "mutation," as this term is used in biology; for, since the heterocatalyst is not self-reproducing, *i.e.*, does not multiply itself, as an autocatalyst does, its modifications also are not self-reproducing, unless, of course, the modification should convert the heterocatalyst into an autocatalyst. Modification of the specificity of an *autocatalyst*, however, would be essentially equivalent to mutation, *provided* the modified catalyst is also specifically autocatalytic *and* specifically different, in respect of its autocatalytic reaction, from the original one.

These qualifications may be illustrated by consideration of an analogous case in the field of crystallization. Suppose a slowly evaporating solution, saturated with respect to a number of different solutes (in the form of ions or molecules or both), in which a number of different kinds of crystals are growing. If we speak of crystal growth as an "autocatalytic" process, simply for the purpose of the analogy, each kind of crystal is specifically "autocatalytic" and specifically different, in respect of its "autocatalytic reaction," *i.e.*, its growth, from every other kind (the specificity referred to is specificity of crystal structure, not necessarily of chemical composition). Now suppose we remove one particular crystal from the solution, and change its composition or constitution in any way, *e.g.*, by chemical substitution or isomeric change, by addition or subtraction of "water of crystallization," etc., and then return the resulting product, whatever its form, to the solution. Now, in regard to the "autocatalytic" (growth) properties of this "modified" material, we may distinguish three cases: (1) It may be non-crystalline, in which case it will be incapable of specific growth, *i.e.*, it will no longer be "specifically autocatalytic." (2) It may be crystalline and isomorphous with the original crystal, in which case it will still be "specifically autocatalytic" (capable of specific growth), but will not be specifically different in this respect from the original crystal; the new material formed, as the

crystal grows, will be identical in the original and the "modified" crystal, the proportions of the two components depending solely on the composition of the solution. (3) It may be crystalline and non-isomorphous with the original crystal, in which case it will be "specifically autocatalytic" and also specifically different in this respect from the original crystal, for it will now have a different specific growth form and will take up different substances from the solution in its subsequent growth: this last case is analogous to mutation. Of course, if some constituent of this "mutant" crystal is not present in this solution, or other conditions (of temperature, concentration, etc.) render this particular crystal form unstable in this solution, it cannot grow here but will, on the contrary, dissolve and may eventually be lost entirely: in biological terms, it is "inviable" under these particular conditions because it is not "adapted" to them, although it might be "viable" (capable of existence and growth) under other conditions.

Now let us imagine a substance of the "organic" type, in the purely chemical sense, made up of several different radicals united by primary co-valence bonds (*e.g.*, a polypeptide, composed of several amino acids), in a solution containing all these radicals in the form of separate molecules (or ions). Let this imaginary substance be endowed with two properties: first, it adsorbs specifically molecules (or ions) identical with its own constituent radicals, in a spatial pattern identical with its own molecular structure, as a salt crystal takes up ions identical with its own constituents in a pattern identical with its own structure; secondly, it catalyzes the *chemical* combination of these adsorbed molecules (or ions) with one another by the same kind of linkages by which its own constituent radicals are united, *e.g.*, if a polypeptide, by peptide linkages between the successive amino acids. The product of this chemical reaction would thus be a molecule identical with that of the original substance, which is therefore a *specific autocatalyst*. This substance would thus continue to increase so long as the conditions (of concentration, etc., as previously discussed) are such as to permit this reaction to proceed in the synthetic direction, as a crystal increases so long as the concentration of its constituents, and other conditions, in the surrounding solution are such as to permit its growth. It need not be assumed, however, that this increase would necessarily be in the usual form of crystal growth, *i.e.*, a massive aggregate: if, for instance, the molecule of the autocatalyst is "flat," with only two (opposite) surfaces at which the specific adsorption can occur, its autocatalyzed increase might take the form of a linear filament, of unimolecular thickness, growing in a line perpendicular to the plane of this molecule; this filament, moreover, might be subject to disruption, *e.g.*, by convection currents, or its own electrostatic charges, etc., so that the autocatalyst might remain colloiddally, or even molecularly, dispersed.

Now suppose some portion, let us say a single molecule, of this autocatalytic substance to undergo a chemical change of any kind (addition, subtraction, substitution, or intramolecular rearrangement). In regard to the effect of this "modification" on the autocatalytic properties of the substance, we have the same three possibilities as in our previous analogy of the crystal: (1) Its autocatalytic property may be destroyed entirely. (2) Its specific autocatalysis may not be altered at all. For instance, if the change consists in the addition of an extra radical to one end of the molecule, the property of specific adsorption may not extend to this new radical, and the molecule may continue to autocatalyze the synthesis of the original substance without this addition; or some relatively slight chemical change in one of the constituent radicals may not destroy its power to adsorb selectively the molecules or ions corresponding to its original form; etc. In this case the modification will not be perpetuated. (3) It may be specifically autocatalytic in the new form, which is specifically different in this respect from the original one. For instance, an intramolecular rearrangement of the constituent radicals may result in a corresponding change in the spatial pattern of the molecules or ions adsorbed, and

consequently of the new autocatalyst molecules synthesized; or an added or substituted radical may share the power of specific adsorption of molecules or ions of its own kind, resulting in their incorporation in the newly synthesized autocatalyst molecules; or the change might be of the nature of polymerization, perpetuated in the subsequent autocatalysis, etc. In this case the modification will be self-perpetuating, provided the surrounding conditions, as previously discussed, permit this. This last type of modification constitutes "mutation," and an autocatalytic substance capable of this kind of change would be a *mutably specific autocatalyst*. It is to be noted that this term does not imply that *every* change in such a substance must be of this kind; most changes would be more likely to be of the other two kinds mentioned above, especially the first.

No indisputably non-living substance or material with the property of mutably specific autocatalysis is known. We say "indisputably" non-living because it is precisely in the disputed border zone between the "living" and the "non-living" that we find the clearest examples of mutably specific autocatalysts, namely, the *viruses*. The propriety of speaking of a virus, even when it is crystallizable, as a "substance" may be questioned, because crystallization is not a sufficient criterion of a pure substance, in the strict chemical sense; but of course the same objection may be raised in the case of any natural protein, or indeed any material whose chemical constitution has not been completely determined. As there is, on the other hand, no evidence that a virus is not a single substance, we may speak of it, non-committally, as a "substance or material," with the understanding that we are speaking of a specific kind of material with certain definite constant properties—chemical, biological, and crystallographic—by which it can always be identified and which survive unaltered such manipulations as isolation, crystallization, colloidal dispersion, and unlimited transfers in series. In any case, this question does not affect the propriety of speaking of a virus as an "autocatalyst," because many catalysts, of course, are not pure substances but "mixtures"—or, better, definite physicochemical combinations—of two or more substances. That a virus is specifically autocatalytic is unquestionable: each virus multiplies specifically (under proper conditions, of course) and is specifically different from other viruses; it differs chemically from the normal components of the medium in which it multiplies, and its multiplication must therefore involve chemical synthesis of the substance or substances of which it is composed, which does not occur unless the virus is initially present. The evidence for mutability of viruses is less abundant, but seems to be quite conclusive in some cases: a particular "strain" of virus, with certain specifically self-reproducing characteristics, gives rise to a new "strain" with different specifically self-reproducing characteristics. The viruses, or at least those in which such mutations have been demonstrated, are therefore mutably specific autocatalysts.

Although the viruses are the only mutably specific autocatalysts which have, as yet, been chemically "isolated," the evidence from genetics and cytochemistry demonstrates quite conclusively that all organisms contain such substances (or materials); indeed, in the higher organisms at least, there are thousands of specifically different ones in each cell—namely, the *genes*. The evidence that the genes are specifically autocatalytic is essentially similar to that in the case of the viruses, though somewhat less direct, in that the genes have not yet been chemically isolated. As they have not been isolated, there is no *direct* evidence that the different genes differ from each other *chemically*, though in view of the large number of specifically different genes any other interpretation seems highly improbable; but this is not essential to their being specific autocatalysts, as specifically different catalysts, in many cases, differ from each other "physically" rather than "chemically." The material ("chromatin") comprising, or containing, the genes differs chemically from the surrounding substances, and multiplies by synthesis of its own components *in situ*. The

individual genes (as identified by their phenotypic effects) are specifically self-reproducing; and the loss of a particular gene entails the permanent absence, not only of the specific phenotypic effects by which it is identified, but also of the particular bit of chromatin material at the point where this gene, when present, is located; that is, this particular gene is necessary for the reproduction of this particular bit of chromatin material, which may be considered to be the gene, although it may also contain additional material not constituting part of the gene: this is largely a question of definition. The evidence that each gene is specifically autocatalytic (under proper conditions, of course) appears, therefore, to be logically complete. The evidence for mutability of the genes (or many of them, at least) is, of course, abundant: the present concept of "mutation" is based primarily on mutations of individual genes, though other kinds of heritable variations may also be included in this term. As mutably specific autocatalysis is *the* essential property of the gene *qua* gene (of which its other distinctive properties may be "by-products"), we shall here call any substance or material having this property a "genic" substance or material.

Genic substances or materials, as thus defined, are present: in the *chromosomes* of all organisms having definite chromosomes; in *bacteria* and similar organisms which have no definitely distinguishable chromosomes, but contain "chromatin" material; in the *viruses* (including the bacteriophages); probably in *plastids*, or at least some of them; and possibly also in other cytoplasmic "formed bodies" or in the "general cytoplasm." What have all these materials in common, aside from the property of mutably specific autocatalysis? There is one feature of *chemical composition* common to all of them and especially characteristic of those materials (chromatin and viruses) which are most certainly genic—namely, the presence of *nucleoproteins*.

It has long been known that chromosomes are composed entirely, or almost entirely, of nucleoproteins, or of nucleoproteins and their components (nucleic acids and proteins). More recent advances in our knowledge of the finer structure and chemistry of the chromosomes have all served to identify the nucleoproteins still more closely with the specifically genic material.⁵ The essential part of a chromosome is the *chromonema*, a very slender unbranched filament containing a single linear series of genes. Each chromosome consists, in different kinds of cells and at different stages, either of a single chromonema surrounded by an "envelope" of non-genic material, or of a bundle of two to many parallel chromonemata with envelope material surrounding the whole bundle and also the individual chromonemata, or sub-bundles of them, within it. Each chromonema is made up of a linear series of alternating segments of chromatic ("euchromatin") and achromatic material. Each of the euchromatin segments of each chromonema contains (or is) a single gene, which is specifically different from all (or most) of the other genes of the same chromonema (the genes in corresponding positions in the several chromonemata of one chromosome are usually identical, having been produced by the specific self-reproduction of a single gene). The intervening achromatic segments apparently consist of non-genic material, probably produced by the adjacent genes. The genic (chromatic) material is composed of nucleoproteins. The achromatic material is composed chiefly, if not entirely, of simple proteins of the "protamine" type, with a longitudinal fibrous structure, probably forming a continuous filament extending throughout the length of the chromonema, to which the individual genes are firmly attached, perhaps by some kind of chemical bonds (*e.g.*, between the acidic nucleoproteins and the basic protamines). The "envelope" material of the chromosomes is composed chiefly, or perhaps entirely, of basic simple proteins of the "histone" type. The large proportions of protamines and histones found, by gross chemical analysis, in condensed chromosomal material, such as sperm nuclei, may therefore have no significance in regard to the composition of the genes them-

selves, being merely "skeletal" and "envelope" materials of the chromosomes. The protein components of the nucleoproteins composing the genic material are, in part at least, "higher" proteins of the "globulin" type, and may perhaps also contain some other prosthetic groups besides the nucleic acid (*e.g.*, iron is generally found in, or closely associated with, nucleoproteins). Some parts of chromosomes, and some whole chromosomes, consist of a different kind of chromatin material, called "heterochromatin," which does not have the typical "banded" structure of alternate chromatic and achromatic segments, but is chromatic throughout. This heterochromatin is also composed of nucleoproteins, with a larger proportion of nucleic acid than the euchromatin regions. The heterochromatin regions are also genic (specifically self-reproducing and mutable), but less differentiated than the euchromatin regions, *i.e.*, containing fewer specifically different genes in proportion to the volume of chromatin.

Bacteria—which are, of course, specifically self-producing and mutable—differ from most other organisms in having no definitely distinguishable chromosomes, but they contain an unusually high proportion (as compared with most ordinary cells, taking the cell as a whole) of "chromatin," *i.e.*, material staining with stains which are more or less specific for nucleic acids. Gross chemical analysis reveals a correspondingly high proportion of nucleoproteins in the bacteria. Relatively little is yet known about the fine structure or composition of bacterial chromatin. Other simple organisms, such as the blue-green algae, which likewise lack definite chromosomes, also always contain chromatin (sometimes forming more or less chromosome-like bodies), but little is yet known of its fine structure or composition in these cases either.

All viruses which have been isolated and analyzed are nucleoproteins, the protein components being "higher" proteins of the "globulin" type, as is probably true also of chromosomal genes, or at least some of them, as previously indicated. If the viruses are "pure substances"—as suggested, though of course not proved, by their crystallization—they are the only pure genic substances which have yet been isolated. In any case, they are the "purest" genic materials yet available for direct chemical analysis. The chemical constitution of any virus is, of course, not yet fully determined, or even very nearly so, any more than is that of any other natural protein.

There is a good deal of apparently conclusive evidence that the plastids of plant cells, or at least some of them, are specifically self-reproducing and mutable. There is also good evidence that they contain nucleoproteins.

The question of the presence of genic materials in the cytoplasm (apart from plastids) is a very complex and quite unsettled one, involving both the problems of "cytoplasmic inheritance" and of "self-differentiation." Apart from the cases of plastid inheritance, the positive evidence for "cytoplasmic inheritance," properly so called, *i.e.*, the persistent hereditary transmission of specifically self-reproducing cytoplasmic components, is meager and generally inconclusive; on the other hand, the whole body of genetic data indicates that cytoplasmic inheritance must be, at best, exceptional. It is still possible to evade this conclusion by appealing from the demonstrable evidence to as yet unverifiable hypotheses; but, for the present at least, we must regard cytoplasmic inheritance as doubtful or exceptional. Should its occurrence, whether general or exceptional, be clearly demonstrated, it must imply the existence in the cytoplasm of some kind of "genic" substances or materials, in the sense in which we are here using the term. The problem of "self-differentiation," *i.e.*, the maintenance and continuation of the differentiation of ontogenetically differentiated cells, tissues, or organs, after their removal from the conditions which may have initiated this differentiation, is one of a different kind: here the facts are, in general, well established, but there are several proposed explanations of them. Some of these explanations postulate specifically self-reproducing cytoplasmic components—whether cytoplasmically inherited or, more probably, originally

produced by the action of the chromosomal genes—while others assume only continuing interaction of the chromosomal genes with differentiated (but not self-reproducing) cytoplasmic components which, originally produced by the action of these genes, condition their subsequent activities. Whatever may be the eventual answers to these questions, we do find nucleoproteins, in greatly varying amounts, in the cytoplasm of many, if not all, kinds of cells. It seems quite significant that the quantity of nucleoproteins in the cytoplasm is greatest in cells which are growing rapidly, or actively engaged in other synthetic processes such as the production of special secretory materials. The concentration of nucleoproteins in the cytoplasm, moreover, is greatest in the immediate vicinity of the nucleus, suggesting their ultimate derivation from the activities of the chromosomal genes.

On the basis of all the present evidence, it thus appears very probable that all known "genic" substances or materials are, or contain, nucleoproteins. This does not, of course, imply that all nucleoproteins are "genic," or that the manifestation of "genic" properties by any nucleoprotein (or material containing it) is independent of surrounding substances and conditions.

The chemical constitution, *i.e.*, molecular structure, of nucleoproteins, like that of other proteins, is still very incompletely known. Nucleoproteins are compounds of simple proteins (polypeptides) with nucleic acids (polynucleotides), though it is not unlikely that some of them may also contain other prosthetic groups, *e.g.*, ferri-ferrous groups. A considerable part of the protein is very loosely bound to the rest of the nucleoprotein, apparently in a salt-like combination, but it is doubtful that this loosely bound protein is really an integral or constant part of the nucleoprotein molecule. Another protein fraction is more firmly bound to the nucleic acid, probably by linkages of the peptide or ester types, *i.e.*, by combination of hydroxyl groups with one another or with amino or imino groups, with elimination of the constituents of water; such linkages might involve the free carboxyl or amino groups, or the internal imino groups, of the protein, and the phosphoric acid or nitrogenous basic groups (or possibly the sugar groups) of the nucleic acid.

Only two different nucleic acids (ribonucleic acid and thymonucleic acid) are yet known; but in view of the relatively few sources from which nucleic acids have been isolated and analyzed, there may well be others: within the general type of structure common to the nucleic acids there is the possibility of numerous variations of composition and constitution. On the whole, however, it is improbable that differences in the nucleic acids can account for more than a very small fraction of the differences between the thousands of specifically different genes in each organism (at least in the higher organisms) and the many millions which must exist in all organisms. On the other hand, the possibilities of differences of composition and constitution between the protein components are practically infinite (of the order of 10^{1000} or even more); and we know that there are specific differences between the corresponding proteins of even closely related organisms, as well as many different proteins in each organism. These considerations, in conjunction with the fact that apparently only nucleoproteins are "genic," suggest the obvious and temptingly simple hypothesis that the nucleic acid is responsible for the general "genic" property, while the protein components are responsible for the specific diversity among genes. But this may well be a gross over-simplification of the actual relations: it is quite probable that at least some part, perhaps some particular groups, of the protein molecule, as well as the nucleic acid, or some essential part of its molecule, and the form of combination between them, may all be equally essential for the "genic" property; variations in the nucleic acids and in the linkages between them and the proteins may also contribute to the specific diversity among genes.

One of the marked chemical properties of nucleic acid is its capacity for polymerization, which may play an important role in the structure of the nucleoprotein molecule. For instance, we might picture a long chain of polymerized nucleic acid

as forming the "backbone" of the nucleoprotein molecule, to which various amino-acids or polypeptides, and perhaps other groups, are attached as "side-chains." On the other hand, the "backbone" of the molecule might be a polypeptide chain, with the nucleic acid, and perhaps other prosthetic groups, attached to it; or it might be a chain of alternate polypeptide and polynucleotide segments; etc. Another possibility is a longitudinal axis composed of parallel polypeptide and polynucleotide chains, linked together all along their lengths to form a series of condensed heterocyclic rings, to which various side-chains are attached. A normal straight-chain polypeptide may be regarded as a series of glycine residues united by peptide linkages, with the various other amino acid residues (minus their carboxyl and α carbons) attached to the α carbons of the glycine as "side-chains." Similarly a polynucleotide is a series of mononucleotides united by ester (or possibly other) linkages: each mononucleotide may be regarded as made up, fundamentally, of a phosphate radical, a pyran (or perhaps a furan) ring, from which the pentose and hexose sugars are derivable, and a pyrimidine ring, from which the purine as well as the pyrimidine bases are derivable. If we assume (merely for the sake of a simple picture) that these polypeptide and polynucleotide chains are united through the glycine and phosphate groups, we might have a fundamentally repetitive chain molecule something like this:

with its main axis running longitudinally, *i.e.*, vertically in the plane of the page, and the side-chains (a_1 , a_2 , . . . , b_1 , b_2 , . . .) extending laterally, *i.e.*, horizontally in the plane of the page: the "a"s representing the various amino acid residues (minus their first two carbons), to which, in turn, other groups may be attached, *e.g.*, through secondary carboxyl or amino groups; the "b"s the various groups substituted in the pyrimidine ring to form the several pyrimidine and purine bases, to which, in turn, other groups, *e.g.*, amino acids, etc., may also be attached; other variations are possible by various substitutions in the pyran (or furan) ring to form different sugars, by variations in some of the linkages, etc. Of course this particular picture of the molecular structure is entirely speculative and is not intended to be suggested as necessarily the most probable one. It is intended, rather, merely to suggest a type of molecular structure with certain features appropriate to a "genic" substance capable of indefinitely continued evolution: namely, the possibility of unlimited increase in complexity, while retaining its essential "genic" property throughout, by continued repetition (by polymerization) of an essentially constant fundamental group (which may be assumed to be responsible for the essential "genic" property), and at the same time the possibility of unlimited specific differentiation, by changes (mutations) in the side-chains (or other substituent groups), consisting in replacements, rearrangements, additions, or subtractions of these groups or parts of them. This principle of repetition with differentiation is found at every "level" of biotic organization: the repetition of fundamentally similar but specifically differentiated genes (together with non-genic material, presumably produced by the genes) to form the chromosome; the repetition of fundamentally similar but specifically differentiated chromosomes (together with non-chromosomal material, presumably produced originally by the chromosomes) to form the cell; the repetition of fundamentally similar but specifically differentiated cells, together with non-cellular material produced by the cells, to form the multi-

cellular organism; and again in the formation of "colonies" and "societies" of multicellular organisms.

The longitudinal axis and the side-chains of this hypothetical "genic" molecule lie in the same plane, so that the molecule is essentially "flat," like those of benzene and many other organic substances, and its autocatalytic multiplication may be assumed to occur by the specific adsorption (and subsequent combination) of its constituent radicals at the "flat" surfaces of the molecule. This would tend to produce a filament of identical molecules (a sort of "linear crystal") extending in a direction perpendicular to the plane of the original molecule; transverse divisions of this filament, *i.e.*, divisions in planes parallel to that of the original molecule, whether autogenous or determined by some external force, would result in numerical increase of discrete particles, either multimolecular or unimolecular, of the "genic" substance. In particular cases, *e.g.*, in the chromosomes, one of the "flat" surfaces of the "genic" molecule may be attached (whether by chemical combination or by adsorption) to the surface of some other material, so that its autocatalytic growth can occur at only one surface; and there may be special conditions causing the separation of these molecules as fast as they are formed, so that the "genic" particles remain unimolecular; but it is not necessary to assume that this is generally true.

The longitudinal dimension of this hypothetical "genic" molecule may be called the "dimension of polymerization," its lateral dimension the "dimension of mutation," and its perpendicular dimension the "dimension of reproduction." Since the reproduction of chromosomal genes takes place in a direction perpendicular to the longitudinal axis of the chromonema, this axis must be in or parallel to the plane of the "genic" molecule, and it seems natural to suppose that it coincides with or parallels the longitudinal dimension of this molecule. From the viewpoint of those who would regard the whole chromonema as a chemically united continuum, in which the individual "genes" are merely locally differentiated regions, the whole chromonema would be a single polymeric "molecule," of the general type postulated above, with the individual "genes" corresponding to its "side-chains," or groups of them. In this view, the achromatic segments of the chromonema are not "non-genic," but integral parts of the genic "molecule," presumably its less differentiated regions; in which case the "backbone" of the molecule must presumably be a polypeptide chain, with the nucleic acids only in the "side-chains."

All the facts of mutation, crossing over, and translocation, however, appear to indicate a very considerable degree of independence for the individual genes. The only genetic evidence apparently contradicting this is that of "position effects" (modification of the effects of one gene by its neighboring genes in the same chromosome); these effects are, however, on the average, relatively slight as compared with those of intragenic mutation, and, though fairly frequent, may still be exceptional rather than general. They are probably comparable to the modification of a specific catalyst by alteration of the "carrier" without change in the specific catalytic group itself. The attachment of the individual genes to the "skeleton" of the chromonema may very well be of a chemical or "semi-chemical" nature: the "loosely bound" protein fraction of nucleoproteins probably represents the "skeletal" and "envelope" components of the chromosomes.

It has been remarked that some chemists consider "the whole ocean and everything in it a single molecule, and fishing a chemical reaction because it breaks up this molecule:" if we are to swallow the ocean, we need not strain at a chromonema. Without presuming, therefore, to define "a molecule," we shall, for purposes of the present discussion, consider "a gene," that is, a chromosomal gene, to be the nucleoprotein material of a single euchromatin segment of a single chromonema (excluding the simple protein "skeletal" and "envelope" material). If we consider this genic material to be made up of polymeric molecules of the general type postulated above, with the longitudinal dimension ("dimension of polymerization") of these molecules

parallel to the axis of the chromonema, and assume that the length of each euchromatin segment is that of a single such molecule, then each of these molecules would be made up of between 200 and 1000 of the "fundamental units" (glycine-mononucleotide with "side-chains"); assuming an average of from one to three amino acid residues to each mononucleotide, such a molecule would have a molecular weight of between 100,000 and 800,000 and a volume of between 60 and 500 ($\text{m}\mu$)³, corresponding to a "diameter" of 5-10 $\text{m}\mu$ on the assumption that the molecule is spherical and compact. The molecular volume so computed is that of such a molecule in the crystalline state, if not hydrated or combined with inorganic ions, etc. In a largely aqueous system (such as the living cell), however, nucleoproteins and similar substances are heavily hydrated and combined with inorganic ions, forming colloidal particles or gels containing a very large proportion of water: nucleic acid, for instance, forms quite a firm gel containing 95 per cent of water, and muscle fibers, which are much more "solid" than chromosomes, contain about 75 per cent of water; the water content of chromosomes is probably somewhere between these limits. The apparent volumes of the "genic" molecules, therefore, when measured either as discrete particles in solution or as components of a gel, would be several times as large as those computed above and their "diameters" perhaps twice as great.

The earlier estimates⁶ of the size of individual genes (in *Drosophila melanogaster*), computed by dividing the total volume of the sperm nucleus (which is simply a compact mass of condensed chromosomes, comprising one haploid set of chromosomes), about $0.25 \mu^3$, by the estimated minimum number of genes in one haploid genome, about 2000-3000, gave a maximum volume per gene of about 100,000 ($\text{m}\mu$)³, or a "diameter" of 50-60 $\text{m}\mu$. These figures, being based on a *minimum* number of genes and the *maximum* volume occupied by them, *i.e.*, the total volume of the chromosomes, are absolute *maximum* values, and never pretended to give any indication of the most probable actual sizes of the genes, although they have been widely misinterpreted in this sense.

It is now evident, however, that the actual size of the individual genes must be much smaller than this. In the first place, it now appears that the number of genes in one haploid genome (of *Drosophila melanogaster*) is probably between 5,000 and 10,000, exclusive of the heterochromatin, in which the number of individual genes cannot be estimated; and there are at least two chromonemata in each chromosome in the sperm nucleus: so the number of euchromatin genes in the sperm nucleus is at least 10,000-20,000. Moreover, the aggregate volume of these genes—after subtracting from the volume of the chromosomes the volumes of the heterochromatin, of the "envelope" material, and of the achromatic "skeletons" of the chromonemata, which probably extend right *through* the euchromatic segments—can hardly be more than 10 per cent of the total volume of the chromosomes, and may be much less. If this genic material contains, like "protoplasm" in general, about 80 per cent of water, the volume of the organic substance of the genes is not more than 2 per cent of the total chromosome volume. This would give not over 5,000,000 ($\text{m}\mu$)³ for the aggregate volume of the "dry" euchromatin genes in the sperm nucleus, or 250-500 ($\text{m}\mu$)³ for each gene, which is within the range of the volumes calculated above for the hypothetical nucleoprotein molecule. Of course these calculations are full of assumptions, and therefore prove nothing; but they suggest that it is quite possible that each individual gene, in the sperm nucleus, *may* be a single molecule, without unduly stretching the usual meaning of the word. Certain genetic data have been interpreted as positive evidence that the individual genes are, in fact, single molecules, at least in the sperm cells of *Drosophila melanogaster*; on the other hand, other genetic evidence, from different organisms, has been interpreted as indicating a "compound," presumably multimolecular, structure of the genes. In neither case, however, does the evidence adduced appear to be conclusive, even for the particular cases directly concerned, as other interpretations of the genetic data are always

possible. Nor is it at all necessary to assume that all genes are alike in this respect, or even that any one gene is so at all times. It is quite conceivable, for instance, that a particular gene might be unimolecular at the time of mitotic division, but multimolecular during the intermitotic stage; or that individual genes might be unimolecular throughout the mitotic cycle in rapidly dividing cells, but become multimolecular in more slowly dividing cells or in mature somatic cells; etc. The only point which here concerns us is that no evidence at present available compels us to assume that "a gene" is necessarily a multimolecular structure.

There is one very general and characteristic biochemical phenomenon, which (so far as I know) has never been satisfactorily explained on any other basis, which might very plausibly be explained on the basis of the unimolecular composition of individual genes: *viz.*, the universal presence in living organisms and their products of specific optically asymmetric substances, in contrast to the racemic mixtures of such substances invariably found in materials of abiotic origin, whether natural or artificial. It is generally agreed that the synthesis of optically asymmetric substances in or by organisms is due to the specific catalytic activity of biocatalysts which are themselves optically asymmetric. But the production of these asymmetric biocatalysts must, in turn, be conditioned by the preexistence of other asymmetric substances, and so on. This course of reasoning, carried to its logical conclusion, points to optically asymmetric genes, or "genic" substances, as the original starting points of these series of asymmetric syntheses. But if the individual gene is, *at any stage of the life cycle*, or has been *at any time in its evolutionary history*, a single molecule, then it must be optically asymmetric (provided it contains any asymmetric carbon atoms at all), for a single molecule cannot be a racemic "mixture." This argument, for what it may be worth, does not require that existing genes be unimolecular at all stages, or even necessarily at any stage, of the cell cycle or the life cycle of presently existing organisms, but merely that they have been unimolecular at some time in their evolutionary history: in other words, that the "original" genes were single molecules. The "original" genic materials, however produced, may have been racemic mixtures, but if each individual genic molecule reproduces itself exactly (in respect to optical asymmetry), then each presently existing type of gene must (at least in the great majority of cases) be derived ultimately from a single unimolecular "ancestor," which is quite probable in view of the vast amount of "chance" elimination in the course of evolution. There may be some other equally plausible explanation of this highly distinctive biochemical characteristic, but if so I am unaware of it.

If, then, we assume that "a gene" *may* be a single molecule, *i.e.*, that a gene *qua* gene is not necessarily a multimolecular structure, the question naturally arises: how complex must such a "genic" molecule be? Or, conversely, how simple *may* it be? Of course we have as yet no direct evidence bearing on this question. On the assumptions made above, a single gene (in *Drosophila melanogaster*), if it is unimolecular, would have a molecular weight of between 100,000 and 800,000, and would consist of between (roughly) 10,000 and 100,000 atoms. These values, of course, represent the maximum sizes of the genes (in this particular organism) and the actual sizes of the gene molecules, or of many of them, may be very much smaller, for all we know. Even if the genes of this organism, and other existing organisms, should be single molecules of such huge size, this does not prove that all "genic" molecules need be so large, or anywhere near it. These genes are, of course, products of a long evolution, in the course of which their chemical, as well as physical, complexity may well have increased greatly above that of their "original" ancestors, just as the structural complexity of chromosomes, cells, and organisms has done. If the genic molecule is supposed to have an essentially polymeric structure, as suggested above, it may be supposed that each of the "fundamental units" making up this "chain molecule" should itself have "genic" properties, and that the simplest

possible gene need therefore be no larger than a single one of these units, *e.g.*, a single mononucleotide combined with one or two amino-acid residues. However, this does not necessarily follow, for the "genic" property might require not merely a certain combination of chemical constituents, but also certain physical characteristics dependent on the size of the molecule: for instance, the isomolecular adsorption process, which we have supposed to be an essential step in autocatalytic synthesis, might require a certain minimum molecular weight and surface area, which would thus determine the size of the "smallest possible" genic molecule, quite aside from the degree of strictly "chemical" complexity which may be essential to the "genic" property.

In existing organisms, the production of complex molecules, such as those presumably composing the genes (as well as other complex biochemical substances), undoubtedly involves a long series of synthetic processes, regulated by a system of specific biocatalysts, which are themselves, in turn, produced by complex interactions between a specific system of genes and a specific cytoplasmic milieu, this whole complex "reaction system" being a product of many millions of years of "adaptive" evolution. The specific autocatalytic synthesis of each individual gene is but the final step of such a complex synthetic process. The "original" genes, however, must be presumed to have been produced, in some way, without benefit of such a pre-existent "adaptive" reaction system.

From the purely mathematical standpoint of the theory of probability, the "spontaneous" formation of any structure, however complex, by the purely fortuitous concatenation of all its constituent elements, in the proper proportions and the proper mutual relations, is always "possible," given sufficient time and the co-existence of all these elements in sufficient concentrations. However, the probability of the "spontaneous" origin, at one step, of a molecule of 100,000 or even 10,000 atoms, of at least 5 different kinds, in certain definite proportions and specific stereochemical relations, from its elementary constituents or from inorganic or very simple organic compounds—while mathematically far greater than the probability of the "spontaneous generation," from the same substances, of a man or an amoeba or even a bacterium—is so remote as to be practically beyond the bounds of credibility. This difficulty would be greatly reduced, of course, if the "original" genes were much smaller molecules, of say 50 to 100 atoms each, comparable, for instance, to the single "fundamental units" postulated above, which might be formed by the combination of substances such as CO, HCN, NH_3 , C_2H_2 , C_2H_4 , H_3PO_4 , etc., perhaps through several intermediate stages. If such molecules were formed "spontaneously," *i.e.*, by abiotic and non-autocatalytic processes, in sufficient concentrations, they might also polymerize to form much larger molecules, since spontaneous polymerization is characteristic of many organic substances (as well as some inorganic ones.)

The problem, thus posed, of the origin of the "first" genes, is merely a more specific formulation, in terms of the gene theory, of the long recognized dilemma which confronts any naturalistic explanation of the "origin of life": which came first—the complex organic compounds (proteins, etc.) which constitute the essential chemical basis of "life" as we know it, or the complex physicochemical structure of the living organism which appears to be the essential basis of the "natural" synthesis of these compounds? Obviously, on any naturalistic explanation, neither could have come "first," in anything like their present complex forms: both the chemical components and the special structure of "living matter," as we know it, must have evolved *pari passu* from much simpler antecedents. Moreover, as remains of living things, apparently not essentially different from some of those still existing, are found as far back in geological time as it would be physically possible for any such remains to be preserved, it seems probable that these first—presumably molecular or ultramicroscopic—antecedents originated under the very different physical and chemical conditions of very early geological periods. In this case, it would seem that they must

have been quite different, chemically as well as physically, from the components and structures of all existing organisms; and that the chemical, as well as the structural, characteristics of living things, as they now exist, have evolved *pari passu* with the geological evolution of the earth.

Without speculating further on the origin of the "first" gene (or "genic substance"), or on its chemical composition or structure, let us take it as "given," and proceed to examine the *necessary* consequences of its essential property *qua* gene, *viz.*, the property of mutably specific autocatalysis, independently of any (other) special chemical or physical properties. We may postulate, to start with, a single "genic substance," even a single "molecule" of such a "substance," assuming nothing about its composition, structure, or properties except that it is, by definition, capable of mutably specific autocatalysis under certain (unknown) conditions, which we must also assume as "given."

We cannot properly speak of a substance as being first specifically autocatalytic but not mutable and later "becoming" mutable: for if it is capable of changing, at any subsequent time, into something different in any way but also specifically autocatalytic, then the original substance is, by definition, mutable. We may, however, for the sake of simplicity, examine first the relatively simple consequences of the property of specific autocatalysis, before considering the far greater complexities introduced by mutability. The "genic substance," no matter how little of it there may be originally—even a single "molecule"—will tend (under proper conditions, of course), by virtue of being autocatalytic, to increase in amount; its rate of increase, moreover, will be (at first) an ever accelerating one, for the more of the genic substance exists the more of it will be formed in any given period of time (other things being equal), *i.e.*, the rate of an autocatalytic process *tends* to be proportional to the amount of the autocatalyst present at any given time (assuming that all of the autocatalyst is "active," etc.).

This increase, however, can occur only at the expense of some other substance or substances, and these must be of certain special kinds: for instance, they must contain the particular chemical elements constituting the genic substance, and presumably they must contain these elements in certain particular combinations, which the genic substance can either incorporate directly into its own molecules, or decompose into fragments which it can incorporate. The total existing quantity of such substances (which we may call its "food" substances) will therefore determine an unsurpassable upper limit to the increase of the genic substance. This limit, of course, may be a variable one, as the quantity of the "food" substances may be increased or decreased by other natural processes, but this quantity must have some finite upper limit, which will determine the absolute limit of increase of the genic substance, remembering that we are assuming for the moment that the genic substance does not mutate.

But there may be other factors which restrict the increase of the genic substance even below this theoretically possible limit. For instance, the genic substance may not be able to increase, or even to exist, in all places where its "food" substances exist: it may be limited by various external conditions, such as temperature, physical state of the milieu, etc.; thus the upper limit of its increase would be determined not by the total existing quantity of its "food" substances, but by the quantity available in those environments in which it can exist and "grow." Its ability to utilize the available "food" substances may be further limited by factors such as the physical form of its growth; *e.g.*, whether it forms compact massive aggregates (like most crystals), two-dimensional laminae, linear filaments, or discrete molecules in solution. Any form which tends to limit the surface of contact with the environment or the facility of dispersal throughout the appropriate environment would thereby tend also to limit the utilization of the available "food" substances.

Another factor, consequent on the autocatalytic process itself, which may tend to inhibit this process, is the accumulation of "by-products": unless the autocatalytic

reaction is an extremely simple one (simple additive combination), it will form other products besides the autocatalyst itself, and such "by-products" usually tend to inhibit the reaction which produces them.

Besides all these factors tending to limit the increase of the autocatalyst, we must consider also those tending actually to decrease it. These will include not only external conditions which may act, in one way or another, to destroy some of the autocatalytic substance, but also, in all probability, a certain amount of spontaneous decomposition. All chemical reactions are, to a greater or less extent, reversible; and, roughly speaking, the more complex a substance is the more unstable it is likely to be. Therefore the genic substance, at the same time that it is forming more of itself by autocatalytic synthesis, will probably also be losing some of itself by decomposition, and its *net* rate of increase, at any given time, will be the *difference* between the rates of these two opposite processes. The rate of decomposition will tend to increase as the amount of the genic substance increases; this is also true, *at first*, of the rate of formation of this substance (because it is autocatalytic); but as the various limiting factors discussed above come into play to inhibit its further increase, the rate of decomposition will gradually overtake the rate of formation, until the two become equal, and the *net* rate of increase becomes zero, *i.e.*, the genic substance will have reached a quantitative *equilibrium* with its environment. This equilibrium may be shifted in either direction by changes in any of the environmental factors which affect either the rate of formation or the rate of decomposition, or both, of the autocatalyst. Thus this substance may increase or decrease *in quantity* from time to time; or, in the case of an extreme change in some essential environmental condition, it may even disappear entirely.

We have now to consider the consequences of the second, and more especially distinctive, aspect of the defining property of the gene—mutability. The meaning of this term has been discussed previously. As there emphasized, it does not imply that *every* change in a genic substance is of the special kind which we call mutation. It seems probable that *most* changes in its composition or structure would result in loss of its essential property of specific autocatalysis: such changes would merely constitute decomposition of the genic substance, which has already been considered. Perhaps other changes would not affect its autocatalytic activity at all: these would be of no significance, since they would not be perpetuated. The term "mutability" implies only that *some* changes, however infrequent, are of the special kind called "mutation": *i.e.*, change of the original genic substance into a different one, which is also *specifically* autocatalytic and *specifically different*, in respect to its autocatalytic reaction, from the original one. We need not here consider the causes or the intrinsic nature of such changes, but merely their consequences.

As the immediate result of a single mutation, we have two *different* genic substances, each tending to increase itself specifically. These two genic substances—the "old" one and the "new" one—may differ in their specific rates of formation or decomposition (or both) under the same conditions, in the kinds of "food" substances they require, in the kinds of environmental conditions most favorable to them, etc. Let us consider first the consequences of a mutation which does not alter the "food" or other environmental requirements of the genic substance. The effective differences between the "old" and the "new" genic substances then reduce, for our purposes, to differences in their specific rates of formation and decomposition. Obviously, the one having the greater *net* rate of increase, under the given conditions, will increase more rapidly than the other. Moreover, since the ultimate limiting factor—the amount of available "food" material—is (by hypothesis) common to the two genic substances, the total possible quantity of these two substances together will be the same as that of either of them if it alone were present. In this sense, either one can increase only at the expense of the other: thus these two genic substances are *in direct, unmitigated competition*. When both genic substances have reached quanti-

tative equilibrium with the environment, their relative amounts will be a simple mathematical function of their respective specific rates of formation and decomposition, regardless of which one was present first.

Thus if the original genic substance had already reached equilibrium before the mutation, the new one must, if it increases at all, partly replace the old one; and if the new genic substance happens to be the one with the greater net rate of increase it will replace the greater part of the old one. As other mutations of this kind occur, the genic substances with greater net rates of increase will increasingly replace, to a large extent, those with smaller net rates of increase. This does not necessarily mean that those with the smaller net rates of increase will be entirely eliminated, but as their equilibrium quantities become smaller they will run an ever greater risk of complete elimination by "accidental" factors—that is, by local and temporary environmental changes of an unfavorable or directly destructive nature. This probability of *chance* elimination, which is obviously greatest for those genic substances existing in smallest quantity, must be especially great for *new* genic substances, *i.e.*, those newly produced by mutation, which exist at first as single molecules. Therefore, once any of the genic substances have reached quantitative equilibrium with the environment (or nearly so), any new genic substance has little chance of ever becoming established at all unless it has an advantage over its competitors because of a greater net rate of increase.

Thus, regardless of what kinds of mutations may occur, or of the relative frequencies of different mutations, only those new genic substances which have this advantage will, in general, replace any of the old ones to any appreciable extent; and the greater this advantage, the greater the extent to which such new genic substances will replace old ones, especially those with the smallest net rates of increase. The general result of such replacement of genic substances with smaller net rates of increase by those with greater net rates of increase, augmented by the probability of complete elimination of those genic substances (whether new or old) with the smallest net rates of increase, must be a practically *continuous increase in the average net rate of increase* of the "population" of competing genic substances considered as a whole. This is, in its simplest form, the principle of *natural selection*. It should be especially noted that this principle involves no new assumption of any kind; it follows directly and necessarily from the property of mutably specific autocatalysis, together with the limitation of the total "population" by environmental factors (especially the available "food" supply). What we have been calling "rate of formation" and "rate of decomposition" are usually called, in speaking of organisms, "reproduction rate" and "death rate" respectively; and the difference between these two rates, which we have called "the net rate of increase" is essentially what is meant by such terms as "survival value" or "fitness." If a population is in complete equilibrium, there is no actual net increase (or decrease) of any of its component types, the relative "fitness" of which is then manifested solely by their relative numbers; but such complete equilibrium can scarcely ever exist for any considerable time in any actual population of organisms, for (even in the absence of any general environmental changes) the occurrence of new mutations and the chance elimination of the rarest types must cause continual shifts, in the general direction of replacement of less "fit" types by more "fit" types, resulting in a practically *continuous increase in average fitness* of the population as a whole. This is (roughly stated) the principle of natural selection, in terms more commonly used by biologists; it differs from our previous statement, as will be seen, only in the replacement of "the net rate of increase" by the term "fitness," which means essentially the same thing.

Returning to our hypothetical primitive "genic substances," we have next to consider the consequences of mutations which alter not merely the rates of formation and decomposition of the genic substance but its relations to its environment, espe-

cially with respect to those environmental factors which chiefly limit its possible increase. Such would be, for instance, a mutation which would enable the new genic substance to utilize in its autocatalytic synthesis "food" substances which the original genic substance had not been able to use, or to exist and multiply under some environmental conditions where the original one could not do so. It is obvious that an immediate consequence of such a mutation would be the mitigation of competition between the new genic substance and the old one: the more they differ in these respects—that is, the less their "food" and other environmental requirements coincide—the less they will compete with each other. This reduction of competition will not only enhance the chances of the new genic substance to establish and multiply itself, but will also raise the limit to which the two genic substances (the old and the new one) together can ultimately increase, and will thus *increase the average "fitness"* (ability to increase) of the "population" as a whole. We should therefore expect that, as successive mutations occur, those new genic substances will be most likely to survive and multiply which differ most, in these respects, from other existing genic substances: and there should thus be a general tendency for the whole "population" (of all genic substances) to become ever more diversified in respect to their environmental relations.

The limit of the decrease of direct competition between different genic substances would be, of course, its complete elimination: as, for instance, if two such substances could exist only in entirely different, mutually exclusive, environments, or had completely different "food" requirements. But even complete elimination of competition is by no means the limit of the advantageous effects of diversification, for different genic substances may also have positively beneficial effects on each other. The most obvious relation of this kind is when one genic substance can utilize as "food" substances some of the "by-products" of another genic substance; this relation will usually be mutually beneficial, as the accumulation of its own by-products would presumably usually be deleterious to the genic substance which produces them. But, beyond this, the relation may be a reciprocal one, *i.e.*, each of two different genic substances may be able to use some of the by-products of the other; or it may be a cyclical relation involving three or more different genic substances, *e.g.*, by-products of substance A may be used as "food" by substance B, whose own by-products are used by substance C, which in turn forms by-products useful to A; or the cycle may be still more complex.*

Reciprocal and cyclical food relations of this kind are, in fact, not exceptional but quite universal among actually existing organisms. We need not here discuss further the varied and complex ecological relations which are possible—and actually exist—among different kinds of organisms; our present point is simply that all these relations, which tend to increase the "fitness" of the population (of all organisms) as a whole, are made possible by *diversification* within this population, that is, between the various kinds of organisms. A second result, therefore, of the principle of natural selection is a *continuous increase of diversification* within the population, as this contributes greatly to the increase in "fitness" of the population as a whole.

We must now consider *how* this progressive diversification can be effected, and this necessitates, in the first place, some consideration of the intrinsic nature of the process of mutation. If, as we have assumed, the original "genic" material is a single "substance," *i.e.*, a chemical compound, any change in it must be, primarily, a chemical change, that is, a change in composition or structure of one (or more) of its molecules. At the same time, any *mutation* must be a change of such a kind as to preserve that special feature (or those special features) of its composition or structure upon which the special property of specific autocatalysis depends. Now, all the pos-

* A well-known case is found in Lichens in which a fungus and an alga live in symbiosis. J. A.

sible kinds of changes which a molecule may undergo are of four general types: (1) *loss* of some portion of the molecule (decomposition); (2) *addition* of something—more atoms, radicals, or other molecules—to the molecule (combination, of which polymerization is a special case); (3) *replacement* of some portion of the molecule by something else (substitution); (4) *rearrangement* of parts within the molecule (isomeric change). If the original genic molecule is as simple as possible, consistent with its essential property of mutable autocatalysis, the possibilities of mutation by loss alone must be extremely limited. The possibilities of mutation by replacement (substitution) or internal rearrangement might be somewhat more extensive, depending on just how complex the original genic molecule is, and just how much its composition or structure can be altered without destroying its essential "genic" property.

It would seem, however, that the possibilities of mutation by addition should be greatest of all, since the addition of something extra would seem, on the whole, less likely to destroy the essential peculiar feature (or features) of the original composition or structure than any of the other types of change. This should be especially true of polymerization, which (as previously suggested) may be of especial importance in the evolution of complex genic molecules. Every mutation by addition (including polymerization) would increase the possibilities of further mutations by replacement (substitution) or internal rearrangement—that is, the more complex the structure of the genic molecule becomes, the greater become the possibilities of diversification among genic substances by subsequent mutations. To put this in another way: if the first genic substances were the simplest possible ones, then the *continuous increase of diversification* among genic substances must involve also an *increase in average complexity* of their constitution, though this does not necessarily mean that the simpler ones will be entirely replaced by more complex ones. We know that living organisms contain extremely complex chemical compounds having many thousands of atoms to the molecule; and the genes, or some of them, *may* be among the most complex of these organic compounds. This need not mean, however, that the "original" genes, or even all now existing genes, must be so complex; for, as we have just seen, we should expect the progressive diversification of the genes, resulting from natural selection, to involve also an increase in complexity of many (not necessarily all) of them. For this very reason, therefore, the extreme complexity of chemical constitution characteristic of many components of existing organisms may itself be a result of a long-continued process of evolution (by mutation and natural selection) from originally much simpler substances.

The possibilities of continued diversification are not limited to the complexity, however great this may be, attainable within the structure of a single molecule. Since even the largest organic molecules are still far below microscopic size, there would seem to be some factor (or factors) limiting their possible size—whether it be inevitable chemical instability beyond a certain size, some feature of the mechanism of their synthesis, or something else. Whatever the nature of this limitation may be, it is evident that the possibilities of greater complexity, and therefore of greater diversification, would be enormously enhanced if the evolution of the gene should overstep the boundary of molecular dimensions, and advance from a molecular to a supra-molecular structure. One way in which this might occur is by the permanent association of several or many genic molecules in a definite multimolecular aggregate: such aggregates may not only attain greater size and structural complexity than single molecules, but have also the possibility of much greater diversification, by independent mutations of the several genic molecules comprising the aggregate, resulting in an internally differentiated aggregate of genic molecules having special chemical and spatial relations to one another; the potential complexity and diversification of such genic aggregates would seem to be almost unlimited. The individual

genes (in the conventional sense) of the higher organisms, or some of them, *may* be such multimolecular aggregates of genic molecules; and the chromosomes are essentially genic aggregates (though probably containing also some non-genic substances): thus there may be multimolecular genic aggregates of several successive "orders."

Another way in which supra-molecular complexity may be attained is by the permanent association of a gene with non-genic substances, *i.e.*, substances which are not themselves autocatalytic but are produced, directly or indirectly, by the activity of the gene. These non-genic substances would presumably be, in the first instance, by-products of the autocatalytic action of the gene. In most cases by-products have an inhibiting effect on the reaction which produces them, but in some special cases the opposite is true. Thus it might happen that some by-product of a particular gene would react with some substance in the environment in such a way as to convert a substance which was not directly utilizable (as "food") by the gene into something that is utilizable, or to "protect" the gene from some deleterious substance or condition, etc. It is evident that any gene which happened to form such "useful" by-products would thereby acquire an "advantage" over other genes—by being able to use a wider variety of "food" substances, or to occupy a greater range of environments, or to survive more unfavorable vicissitudes, etc.—and would thus have a better chance to survive and multiply. We might expect, therefore, in the course of time, by successive mutations and the operation of natural selection, a continuous increase in such "useful" by-products and in their diversity and complexity. In the case of an internally differentiated aggregate of genes, the possibilities of such "useful" by-product systems are obviously still more diverse and complex—by reactions of one gene with by-products of another, reactions between by-products of different genes, between these by-products or their secondary products and environmental substances, etc.

By a combination of these processes—the aggregation and differentiation of genes, and the elaboration of a complex envelope of non-genic substances produced (directly or indirectly) by the activity of the genes—the complex structure of the *cell*, typical of most existing organisms, may have been gradually evolved. *Pari passu* with the structure of the cell must evolve the process of *cell division*, by which the cell reproduces itself *as a whole*, maintaining the quantitative and spatial relationships of its various genes and non-genic components. Some of the stages in this evolution of the cell and the process of cell division seem to be represented by the simplest existing microscopic organisms—the bacteria and the blue-green algae. Along with increasing complexity of chemical composition, structure, and reproductive processes must also go increasing complexity and diversity of metabolism, physical activities, and responses, all these being, primarily, means of enabling the organism to utilize different kinds of food substances and inhabit different kinds of environments, thus mitigating the severity of competition and thereby enhancing the increase of the "population" as a whole.

Just as the individual genes, *i.e.*, the molecules or unit particles of genic substances or materials, are limited to ultramicroscopic dimensions, the individual cells are limited (with some exceptions) to microscopic dimensions. In this case, the principal limiting factor seems to be the quantitative relation between the volume and the surface area of the cell. But just as the limitations of size, and therefore of complexity and diversity, of the individual gene have been overcome by the evolution of the polygenic cell, so the limitations of the individual cell are, in turn, surmounted by the evolution of the *multicellular* organism. This evolution is a repetition on a higher level (so to speak) of the same kinds of processes as those involved in the evolution of the cell from the single gene: the aggregation of cells in definite spatial relations, differentiation (structural and functional) among these cells, and the elaboration

of non-cellular substances about and between the cells. This further increase in structural complexity is again accompanied by increasing complexity and diversity of the processes of nutrition, growth, and reproduction, and of the activities and responses of the organisms—all of which, again, enhance the possibilities of their “making a living” in different ways and under diverse conditions. This same kind of evolutionary process is repeated again, to some extent, on a still higher level, in the evolution of “colonies” and “societies” among some kinds of multicellular organisms.

The argument of the preceding paragraphs may be summarized, briefly, as follows. Given a substance or body with the property of *mutably specific autocatalysis*, the limitation to its increase necessarily imposed by a finite environment results in the operation of the principle of *natural selection* upon its various mutant “descendants.” From this follow: (1) continuous increase in average “fitness”—ability to survive and multiply—of the “population” (of all these descendants) as a whole; (2) continuous increase of diversification within this population, because this contributes greatly to the increase in “fitness” of the population as a whole; (3) increase in average complexity of the members of this population, because this makes possible continued increase of diversity among them. These results of natural selection—“fitness” (adaptation), diversity, and complexity—are, together with hereditary specificity (which is a direct consequence of specific autocatalysis), the most characteristic general features of living organisms as we know them.

At just what stage of complexity we should recognize such substances or bodies as “living” would seem to be a rather arbitrary matter. If we do not choose to recognize the simplest possible bodies (perhaps single molecules) which are mutably autocatalytic as “living,” then we may say that “life” is a result of an evolutionary process identical, in essentials, with that by which the higher organisms have been derived from the lower, and by which populations of existing organisms are continuously modified at present. If we suppose that the property of mutable autocatalysis pre-requires a fairly high degree of complexity, at least in chemical constitution, then the first mutable autocatalyst may itself have been the product of a long process of “evolution”—in the general sense of gradual natural change—by which it had been built up little by little from simpler substances. This process, however, whatever its nature, must be something essentially different from what we call “organic evolution,” the essential factors of which are mutation and natural selection. It is at the moment when the property of mutability first appears that the principle of natural selection begins to operate, and the nature of the “evolutionary” process changes radically to that characteristic of living organisms—the process of *organic evolution*. It might, then, appear most logical, at least in the light of our present knowledge, to draw the line between the “lifeless” and the “living” at this point—to regard as “living” any substance or body which is specifically autocatalytic and mutable. By this criterion, “life” would be coextensive with the process of organic evolution, of which all its complex and diverse manifestations are products—we might almost say, incidental by-products. And the primary physico-chemical basis of organic evolution—and hence, by this definition, of “life” also—is the phenomenon of *mutably specific autocatalysis*.

Notes

1. Recent advances in a number of these fields are reviewed in other chapters of this volume.
2. These are discussed by J. Alexander elsewhere in this volume.
3. This comparison and its possible bearing on biological problems were discussed many years ago by Troland (1917).
4. A more definite picture of a suggested autocatalytic mechanism of this sort was presented by Alexander and Bridges (1928).
5. The very brief summary of the fine structure and chemistry of the chromosomes which follows is based chiefly on the work of Bridges (1935) and the recent review by Schultz (1941).
6. Morgan (1922); Muller (1929); Plunkett (1930).

Appendix

TABLE OF NUCLEAR PROPERTIES AS OF JAN. 1, 1943 *

From "Introduction to the Atomic Nucleus,"

by Robley D. Evans, Mass. Inst. of Tech.

Nuclei which have both stable and metastable states are listed on a single line. In such cases only the half-life, type and energy of the radiations are associated with the metastable (isomeric) state. The mass, abundance, and nuclear moments refer to the stable state.

Two lines are devoted to each nucleus which has two radioactive states (ground state and isomeric state).

Symbols used: Radioactive transactions are denoted as follows: $\alpha = \alpha$ ray; β^- = negatron continuous β ray spectrum; β^+ = positron β ray spectrum; e^- = internal conversion electrons; γ = nuclear gamma rays or isomeric transition; K = orbital electron capture.

Energies are given in MEV. For continuous β ray spectra the extrapolated upper limit of energy is given.

Nuclear moments. I = total nuclear angular momentum in $h/2\pi$ units; μ = magnetic dipole moment in nuclear magnetons, $eh/4\pi Mc$; q = electric quadrupole moment in $10^{-24}cm^2$ times the electronic charge. All masses are for the neutral atoms, on the physical scale $0^{16} = 16$.

* Just to show what results may be expected to emerge from the data here tabulated, the age of the potassium atoms in a sample of K obtained from the Pultusk meteorite has been determined by the use of the long-lived beta emitter (K_{40}) and found to be the same as telluric K, thus indicating that this meteorite is of the same age as the solar system (W. C. Schumb, R. D. Evans and W. U. Leaders, J. Am. Chem. Soc., **63**, 1203 (1941)). And the percentage of K in a sample may be determined from its radiation as registered by a Geiger counter (R. B. Barnes and R. J. Salley, Ind. Eng. Chem., Anal. Ed., **15**, 4-7 (1943)). Editor.

Index to Subjects

A

- Abbe theory of microscope, 165
- Aberration, chromatic, 161
- Aberration, diffraction, 165
- Aberration, spherical, 161
- Abnormalities, natural and induced, 584
- Acacia, use in hypoproteinemic edema, 906
- Accelerating lenses, 163
- Accretion, growth by, 11
- Acenaphthene, 586
- Acetaldehyde, 560, 561
- Acetobacter suboxidans*, 558
- Acetoin, 727
- Acetone, 21
- Acetyl aneurin, 692
- Acetylcholine, 578, 579, 580, 691, 692, 745
- Acetylcholine, release of, 898
- Acetylene black, 206, 435, 438
- Acetylene tetrabromide, 21
- Achaete, gene, 824
- Acid aura, of protozoans, 1165
- Acid-amine mixtures, 74
- Acide cellulique, 618
- Acid-forming foods, 719, 720
- Acridine, 588
- Acridine, as sensitizer to light, 588
- Acrylic ester polymers, 281
- Action currents in nerves, 764
- Action potentials in nerves, 588
- Activated state, 238
- Activators, chemical, 578
- Activation, energy and volume changes of, 240
- Activation, in polymerization, 283, 284
- Active muscle, changes in, 883, 884, 885
- Active muscle, heat in, 884, 885
- Adamsonia* fibers, 654
- Adaptation, 1175
- Adaptive enzymes, 561
- Adenocarcinoma, 996, 997
- Adenosine triphosphatase, 533
- Adenosine triphosphate, 689, 672, 884, 885, 898
- Adenylic acid, 884, 885
- Adhesion, under pressure, 333
- Adrenal cortical hormones, 701
- Adrenal cortex, 740, 747
- Adrenal medulla, 740
- Adrenalin, 745
- Adrenals, in age, 1060
- Adrenotropic hormone, 744
- Adsorbents, 461, 462
- Adsorption, 97
- Adsorption and antibody production, 962
- Adsorption and crystallization, 443
- Adsorption isotherm, 449, 971, 972
- Adsorption isotherm, new, 98
- Adsorption of gases on solids, 434
- Adsorption, selective, 457
- Adsorption, specific, 968
- Adsorption theory of photographic development, 500
- Adsorption, types of, 453
- Aeneas, sculpture by Bernini, 1051
- Aerobiology, 1100
- Aero-empysema, 1082, 1085
- Aerosols, 109
- Aerosols, coagulation of, by ultrasonics, 356, 360
- Aerosols, from respiratory activities, 1101
- Aerosols, infective, 1099
- Aerosols, physical stability of, 1105
- Aerosols, viability of, 1106
- Aetiozymase, 688
- Agate, 516
- Agave* fibers, 654
- Age and cancer, 1036
- Age and diet, 1062
- Age and resistance, 1062
- Ageing and wisdom, 1053
- Ageing, nature of, 1051
- Ageing of unicellular organisms, 1052
- Ageing, progressive changes in, 1052
- Agglutinates, 965
- Agglutinin, egg, 852
- Aggregation in colloids, 115
- Aggregation of paraffin chain compounds, 266
- Aggregations in gases, by ultrasonic waves, 356
- Aggregations in liquids, by ultrasonics, 357, 364
- Air-borne infections, experimental, 1113
- Air, disinfection of, 1109, 1111, 1114
- Air filters, to prevent infection, 1109
- Air-locks, in electron microscope, 180
- Air-raid shelters, air in, 1111
- Air sampling, 1101
- Akanthias*, 1063
- Alactoid contraction of muscle, 888
- Albinism, 817
- Albite, 541
- Albumin-euglobulin ratio, 1160
- Albuminocholia, 1080
- Alcohol addicts, 727
- Alcohol, and time sense, 782
- Alcohol, hydrogen bonds in, 96
- Alcohols, catalytic production of, 553
- Alcohols, effects of on monolayers, 69
- Aleuronat, 944
- Alfalfa mosaic virus, 786, 806
- Alga, sexual change in, 570
- Algae, cellulose in, 637
- Alkali metal emulsions, 350
- "Alkaline" foods, 720
- Alkalized catalysts, 552, 553
- Alkaptonuria, 588
- Allel, 816
- Allelocatalytic reaction, 1165
- Allelomorph, 816
- Allergen, 979
- Allergy, 979 *et seq.*
- Allergy, heredity, 588
- Allium cepa*, 621
- Allotropic forms, 6
- Alloxazine mononucleotide, 699
- Alumina, as carrier, 552
- Alums, adsorption of dyes by, 447
- Amandin, constants of, 566
- Amalgamation of iron, 334
- Ameba, and acid, 1164
- Ameba cytoplasm, 876, 878
- American dietaries, 728, 729
- Amidol, 487
- Amine, in ultracentrifuge, 432
- d*-amino acid oxidase, 698, 699
- Amino-acid residues of proteins, 536, 537, 543
- o*-aminoazotoluene, as carcinogen, 1003
- p*-aminobenzoic acid, 702, 730, 739
- 2-Amino-5-diethylamino-toluene, 483
- p*-Aminodiethylaniline, 483
- p*-Aminophenol, 483
- Ammonia, catalytic production of, 550, 551, 552
- Ammonium alum, adsorption of dyes by, 447
- Ammonium nitrate explosives, 249
- Amoebae*, 862
- Amoeboid glia, 1138
- Amontons' law, 247
- Amorphous state, 308
- Ampholytic nature of phosphatides, 1122
- Amurotic idiocy, 588
- n*-Amyl alcohol, 553
- n*-Amyl bromide, 272
- β -amylase, in soybeans, 681
- Amylose, 667, 669, 671, 675, 680

Amylose, adsorption of, by cellulose, 668
 Amylopectin, 667, 668, 671, 675, 680
 Anaerobic glycolysis in cancer, 1001
 Analysis, capillary, 459
 Analysis, chemical, 457
 Analysis, chromatographic, 459
 Analysis, ultracentrifugal, 411, 432
 Anaphase, 816
 Anaphylactic reaction, in guinea pigs, 981
 Anaphylactogen, 979
 Anaphylatoxin, 983
 Anaphylaxis, 979 *et seq.*
 Anaphylaxis in various animals, 980
 Anaphylaxis, relation to inflammation, 983
 Anatase, 97
 Anauxite, 193
 Androgenesis, 581
 Androgen control of prostatic cancer, 590
 Anesthesia, Mg and Ca in, 712
 Anesthetics, action of, 1143
 Angle centrifuge, 420, 428
 Aniline emulsions, 351
 Animals and anaphylaxis, 980
 Animal pole, 853, 856, 857
 Anion-active colloidal electrolytes, 102
 Anomalous viscosity and ultrasonic waves, 354
 Anorthite, 541
 Anoxia, in brain, 1144
 Anthracene, 465
 Anti-blacktongue factor, 693
 Antibodies, 957
 Antibodies, formation of, 570
 Antibodies against cancer, 1004
 Antibodies, chemical nature of, 959
 Antibodies, in ultracentrifuge, 432
 Antibodies, molecular weights of, 959
 Antibodies, production of by adsorption, 962
 Antibodies, reaction to non-antigens, 963
 Antibodies, specificity of, 957
 Antibodies, stereo factors in, 958
 Antibodies, valence of, 961
 Antibody-antigen reaction, 964
 Antibody, electrophoresis of, 409
 Antibody formation, 841
 Antibody molecules, shape of, 964
 Anticatalase, layers of, 88
 Antidromic impulses, 929
 Antigen-antibody films, 961
 Antigen-antibody precipitate, composition of, 977
 Antigen-antibody reaction, in electron microscope, 230, 231
 Antigen-antibody reaction, conditions influencing, 975, 976
 Antigen, as mould for antibody, 570, 571
 Antigen molecules, shape of, 964
 Antigens, 957, 962
 Antigens, polyvalency of, 961
 Antigens, specificity of, 964
 Antigenicity, nature of, 962
 Antigorite, 193
 Anti-hemorrhagic vitamin, 734
 Antilysin, 971
 Antipneumococcus serum globulins, constants of, 565, 566
 Antirachitic vitamin, 734
 Anti-sera, in electron microscope, 224
 Antisera, specific adsorption of, by bacteria, 574
 Antitoxin, 959
 Anti-typhoid serum, 225
 Antiviral antibodies, 970
 Ants, 595
 Ants, sex in, 581
 Aplastic anemia, blood in, 408
 Apples, 583
 Apples, internal cork of, 559
 Apples, little leaf of, 559
 Applied mathematics, 6
 Arachidic acid, 47, 244
Arbacia, 923, 932
Arbacia eggs, 867, 869, 870, 876, 877
 Arca, 564
 Area of monolayers, 85
 Areas of surfaces, determination of, 434
Arenicola, 563, 567
 Arginine, 537, 543, 562
 Argentine, varves in, 525
 Armadillo, polyembryony in, 575
 Arrow black, 435, 438
 Arsenic sol, flocculation of, by iron oxide sol, 970
 Arteries, in age, 1055

Arthus phenomenon, 982, 983
 Artifacts, microscopic, 634
 Artificial pearls, 518
 Artificial silk, 612, 613, 614, 624
 Arrhenius equation, 767, 768, 772,, 773, 776, 777, 778, 780, 781, 783
 Asbestos, 201
 Ascidian blood, 558
Ascophyllum, 638
 Ascorbic acid, 703, 730
 Ascorbic acid, effect on collagen, 730
 Asparagine, 537, 538
 Aspartic acid, 537, 538
Aspergilli, 586, 638
 Asphyxia, 1141
 Asphyxia in guinea pig anaphylaxis, 981
 Association (A) polymerization, defined, 281
Astacus muscle fibers, 897
Asterias oocytes, 880
 Atavism, 816
 Atomic structure of solids, 122
Atta, 581
 Attapulgit, 204, 205
Aucuba japonica, 638
Aucuba mosaic virus, 786
 Autocatalysis, 858, 1176
 Autocatalysis and cancer, 1044
 Autonomic nervous system and homeostasis, 993
 Autoradiography, 377, 379
 Auxins, 583
 Aviator's aero-emphysema, 1087
 Aviators, conditioning of, 1091
 Avidin, 1160
 Avogadro constant, 413
 Axon reflexes, 929
 Axoplasma, 1148
p-azoxyanisole, 272

B

Bacillus anthracis, 221
Bacillus delbrückii, 687, 690, 700
Bacillus influenzae, 696
Bacillus macerans, 675, 681
Bacillus megatharium, 221
Bacillus Phlei protein, constants of, 564
Bacillus prodigeosus, 806
 Backcross, 816
 Bacteria, 1183
 Bacteria, effects of pressure on, 332
 Bacteria, in air, 1105
 Bacteria, in electron microscope, 220, 222
 Bacteria, invasion by, 943
 Bacteria, invasiveness of, 944
 Bacteria, specific adsorption of antisera by, 574
 Bacterial dissociation, 568
 Bacterial flavoprotein, 700
 Bacterial sensitivity, 1109
Bacteriodes fundiformis, 569
 Bacteriophage, 428, 786, 806
 Bacteriophage, in electron microscope, 223
Bacterium tumorfaciens, 1030
 Bakelite, 281
 Bakelite, etched, 214
 Balances, for film study, 35
 Ballas, 7
 Banana starch, 669
 Bananas, 583
 Bar gene, 812, 824
 Barium stearate, 127
 Barium stearate films, 88
 Barley globulin *a*, 564
 Barley globulin, constants of, 565
 Barley starch, 669
 Basal metabolic rate, 1052
 Base-exchange, 193
 Base-forming foods, 719, 720
 Bats, flight of, 3
 Bauer equation, 515
 Beer-time, 782
 Bees, sex in, 581
 Beetleling of cellulose, 630
 Beidellite, 193, 197, 198, 199
 Belling's hypothesis, 832, 833, 838, 847
 Bence-Jones proteins, constants of, 565
 "Bends," 1082, *et seq.*
 Benign tumor vs. cancer, 995, 998
 Bentonite, 193, 197, 198, 200, 201, 202, 203
 Bentonite, electric double refraction of, 789
 Benzanthrane derivatives and cancer, 1017, 1023

- Benzene, 465
 Benzene, emulsion of, 346, 351, 352
 Benzene, spreading of, 15, 19, 21, 22
 Benzoic acid, elimination of, 587
 Benzopurpurin, 111
 Benzopurpurin dispersions, 355
 1, 2-benzpyrene, 466
 3, 4-benzpyrene (same as 1, 2-benzpyrene), 590
 Benzpyrene and cancer, 1017
 Benzpyrene cancer, 1004
 Berger rhythm, 579, 765, 766
 Beriberi, 683, 685
 Beryllium, breakdown of, by cyclotron, 377
Betabacterium vermiforme, 570
 Betatron, 380
 Betatron, in medicine, 385
Beta vulgaris, 623
 Bier's spots, 921
 Bile, 750
 Bile pigments, 703
 Bile salts, as detergents, 605
 Bilharzia and cancer, 1019
 Biocatalyst chains, 559
 Biocatalysts, 556, 683
 Biocatalysts, modification of, 568
 Biochemical constitution of cancer tissues, 1001
 Bioelectric effects, 579
 Bioelectric potentials, 762
 Biological action of flavoproteins, 700
 Biological action of "gas," 1094, 1096
 Biological activity of thiamine and cocarboxylase, 687
 Biological effects of bivalent ions, 58
 Biological effects of ultrasonics, 370
 Biological fluids, surface tension of, 100
 Biological polymers, 303
 Biological rates, 770
 Biological units, 9
 Biophores, 593
 Bios, 597
 Biotin, 597, 684, 702, 729, 1160
 Biotin, in cancer, 1002
 Biotin, structure of, 730
 Bipotential lenses, 163
 Birefringence, intrinsic, 754
 Birefringence of lecithin, 1131
 Bivalent ions, biological effects of, 58
 Black carbon, structure of, 128
 Black phosphorus, 331
 Black powder, 249
 Black silver, 506
 Blackman reaction, 602
 Blacktongue, 693, 697
 "Blast," effects of, 1095, 1097
 Blastomere, 816
 Blastula cells, coherence of, 574, 575
 Blastula, divertula from, 575
 Blastula, invagination of, 575
 Bleeding, use of acacia in, 906
 Blood, a fluid matrix, 986
 Blood and sea water, 707
 Blood, aeration of, 1085
 Blood, capillary circulation of, 900
 Blood, coagulation of, 951
 Blood coagulation, effect of pressure on, 332
 Blood, coenzyme content of, 696
 Blood, electrophoretic study of, 406
 Blood, gas emboli in, 1083
 Blood, gases in, 1083, 1085
 Blood, in age, 1061
 Blood, in insanity, 1139
 Blood, in psychiatry, 1154
 Blood, maintenance of neutrality, 992
 Blood pigments, 563
 Blood plasma analysis, 518
 Blood plasma, electrophoretic pattern of, 397
 Blood, role of, 986
 Blood sugar and brain waves, 774
 Boarts, 6
 Bone, cancellous, 747
 Bone marrow, in inflammation, 936
 Bone, salts in, 713
 Bone, structure of, 583
 Bones, as organs, 713
 Bones, calcium storage in, 991
 Bones, fixation of radio-elements by, 378
 Bones, in age, 1060
 Bordet-Gengou media, 569
 Borna disease virus, 806
 Borocetrin, 558
 Boron, traces, 558, 559
Bostrychia, 638
 Boundary friction, 247
 Boundary lubrication, 247
 Bragg formula, 127
 Brain, and endocrines, 1145
 Brain, and vitamins, 1145
 Brain colloids and oxygen, 1144
 Brain colloids, degree of dispersion, 1138
 Brain, electric activity of, 1151
 Brain, electrical behavior of, 1149
 Brain, in age, 1056, 1057
 Brain swelling, 1137
 Brain, pH of, 1150
 Brain volume and skull capacity, 1145
 Brain waves, 765, 766, 772, 774, 778, 1151
 Branched molecules, in starch, 667
 Brachiopods, 595
 Breast cancer, 1009, 1010
 de Broglie equation, 515
 Bromcamphocarbonic acid, 556
 Bromides, action of, 1143
 Bromoform, 21
 Bronchospasm, in anaphylaxis, 982
 Brown-Pearce carcinoma, 1005
 Brown-Pearce tumor, 1031
 Brownian motion, 175, 298, 414, 554, 871, 1089
 Browning, of cauliflower, 559
 Brucella antigen, 976
 Brucite, 192
 Brush heap structure, 115
 Buckwheat, as sensitizer against light, 588
 Bubbles, collapse of, 348
 Bulk rubber, structure of, 293
 Bubbles, critical size of, 1086
 Bubbles, growth of, 1084, 1086
 Buna, 281
 Burns, treatment of, 916
 Bush sickness, 559
Busycon, 806
 Busycon hemocyanin, 226, 228
 Butadiene polymers, 281, 303
 Butanol in starch separations, 668, 675
 Butterfly wing, 191
 Butter-yellow, as carcinogen, 1003, 1018
iso-Butyl alcohol, 553
n-Butyl alcohol, 553
n-Butyl mercaptan, 3
 Butyl bromide, 272
 Butyl rubber, 303

C

- Cadmium bromide, 333
 Calciferol, 67, 734
 Calcification, enzymes in, 560
 Calcium carbonate, crystal forms of, 444
 Calcium, effects of on cell walls, 866
 Calcium, free, in cells, 852
 Calcium, in blood coagulation, 952
 Calcium, homeostasis of, 991
 Calcium infarct, 1067
 Calcium, in nutrition, 711
 Calcium, in the egg, 852
 Calcium oxalate, crystal forms of, 444
 Calcium stearate, 47, 60
 Calcium stearate films, 87
 Calcosphaerites, 611
 Calculi, 1063
 Collier constant, 507
Calocarus, 566
 Canal viscosimeters, 50
 Canary pox virus, 806
 Cancellous bone, 747
 Cancer, 589
 Cancer, a growth problem, 1042
 Cancer and age, 1036
 Cancer and antibodies, 1004
 Cancer and autocatalysis, 1044
 Cancer and bile acids, 1024
 Cancer and cellular autonomy, 1046
 Cancer and chronic irritations, 1014
 Cancer and complement fixation, 1004
 Cancer and diet, 1037
 Cancer and differentiation, 1041
 Cancer and dyes, 1003
 Cancer and estrogens, 1013
 Cancer and frogs, 1033
 Cancer and hormones, 590, 1013, 1014
 Cancer and liver extracts, 1025

- Cancer and metazoan parasites, 1019
 Cancer and phenanthracene derivatives, 1017
 Cancer and physical agents, 1019
 Cancer and polycyclic compounds, 1017
 Cancer and radiation, 1019
 Cancer and regeneration, 1043
 Cancer and Roentgen rays, 1019, 1039
 Cancer and somatic mutation, 1039
 Cancer and tape-worm, 1019
 Cancer and unicellular organisms, 1022, 1023
 Cancer and viruses, 1030
 Cancer and warts, 1027
 Cancer and X-rays, 1019
 Cancer, ascorbic acid in, 1003
 Cancer, avidin in, 1003
 Cancer, biotin, 1002
 Cancer, carbohydrate metabolism in, 1001
 Cancer, causes of, 1005, *et seq.*
 Cancer, causes and nature of, 995
 Cancer, cell division in, 1021, 1022
 Cancer, gradual development of, 1025, 1026
 Cancer, heredity in, 1006
 Cancer, hormones in, 1006, 1015, 1016, 1025
 Cancer, immune mechanisms in, 999
 Cancer, in plants, 586
 Cancer in plants, developed by a "chemical," 586
 Cancer, irreversibility of, 1047
 Cancer, K isotopes in, 1003
 Cancer, kinds of, 996
 Cancer, mammary, 1009, 1010, 1025
 Cancer, milk factor in, 1006
 Cancer, ovarian influence in, 1007
 Cancer, prostatic, 1013
 Cancer, stereoisomers in, 1002
 Cancer, stimulating factors in, 1014

Leucomostoc mesenteroides, 570
 Leucoplasts, 650
 Leukemia, 377
 Leukemia, blood in, 407
 Leukemia, defined, 1031
 Leukemia, of fowls, 1002
 Leukocidin, 944
 Leukocytes, migration into inflamed tissue, 929, 930, 933, 936
 Leukocytosis and leukotaxine, 933
 Leukocytosis-promoting factor, 936
 Leukoderma, induced chemically, 582
 Leukoprotease, 938
 Leukotaxine, as permeability factor, 922, 923, 931, 933
 Leukotaxine, isolation of, 924, 925
 Leukotaxine, properties of, 924
 Lewinite, 1095
 Lichens, 597, 1193
 Liesegang rings, 496, 513
 Liesegang rings and calculi, 1072, 1075, 1077, 1080
 Liesegang rings, theories regarding, 514, 515
 Life and change of state, 861
 Life and states of protoplasm, 859, 861
 Life, criteria of, 1181
 Life, definition of, 1173
 Life of bubbles, 1088
 Life, origin of, 1189
 Light, and sex reactions, 1172
 Light-dark field transition, 170
 Light-sensitization, 588, 589
 Light, sensitization against, 588, 589
 Lignin and cellulose, 634
 Lily bulb starch, 669
Limulus blood, 558
Limulus hemocyanin, 227, 228, 415, 421
 Linear order of genes, 821
 Linkage, in genetics, 809, 817

Lipacalc, 1059
 Lipides and colloids, 1126
 Lipides and dyes, 1130
 Lipides, heat denaturation of, 1132
 Lipides, physical chemistry of, 1119
 Lipohumors, 579
 Lippmann emulsions, 147, 207, 210, 491
 Liquid crystals, 1134
 Liquid paraffin chain compounds, 271
 Liquid phase, condensed, 30
 Liquid phase, expanded, 27
 Liquid phase, intermediate, 28
 Liquid surfaces, films, 12
 Liquids, degassing of, 367
 Liquids, "holes" in, 239
 Liquids, viscosity of, 236, 239
 Lithium chloride, effects of on eggs, 853, 856
 Lithium tritide, 377
 Lithium, under pressure, 335
 Little leaf of apples, 559
 Liver aldehyde oxidase, 699, 700
 Liver and protein storage, 990
 Liver, chemical changes in, 587
 Liver, in age, 1054
 Liver, oxidation by, 559
 Liver substance and cancer, 1018
 Local activators, 739
 Locus, in genetics, 817
Lophius, 1151
 Lorentz equation, 155, 159
 Lorol, 1111
 Louping ill virus, 806
Loxocephalus, 1165

 Magnesium-calcium antagonism, 1144
 Magnesium bentonite, 197, 200, 201
 Magnesium, in nutrition, 711
 Magnesium oxide, electron micrograph of, 185
 Magnesium, traces, 558
 Magnetostriction, 342
 Magnetostriction sound generators, 343
 Magnetostrictive sound generators, 339, 342
 Magnetic lenses, 155
 Maize, genetics of, 825
 Maize, lazy, 583
 Malignant tumors, 995
Malacostraca, 563
 Maltase, 546
 Mammalian hemoglobin, 563, 565
 Mammary cancer, 377
 Manganese, traces, 580
 Manic depressive type, 1158, 1159
 Mannose, 561
 Marchi method, 1148
 Margarinic acid, 47, 85
 Margarinic nitrile, 29
 Mathematics, use of, 5
 Masks, to control infection, 1107
 Matter, structure of, 1
 Maturation division, 817
 Mechanical stress, effects of, 327
 Mechanoreceptors, 765
 Medical use of ultrasonics, 369
 Megatherium bacteriophage, 806

Meiosis, 817
 Melanin, 582
 Melanin formation, 702
 Melanophores, 579
 Melons, 583
 Melting process, in paraffin chain compounds, 271
 Membranes, permeability of, 580
 Membranes, plant cell, 610
 Mercuric fulminate, behavior under pressure, 336
 Mendel's first law, 808
 Mendel's second law, 809
 Mercury, action of on iron, 334
 Mercury, emulsification of, 346, 349, 363
 Mercury fulminate, 249
 Mercury isotopes, separation of, 257
 Mercury, spreading of liquids and solids on, 20
 Mercury vapor, as photographic developer, 472
 Mercuric sulfide, red and black forms of, 331
 Mercury telluride, 333
 Mesitylene, 21
 Mesoderm, 853
 Mesoderm, formation of, 575
 Mesomorphic forms in paraffin chain compounds, 271, 279
 Mesomorphic forms of sodium soaps, 273, 279
 Mesomorphic state, 266, 309
 Mesomorphic state, of virus, 786
 Mesotron, 9
 Metabolism, in cancer cells, 1001, 1002
 Metabolism and electric potentials, 762
 Metabolism, rate of, 858
 Metabolism rate, and organization, 858
 Metabolites as organizers, 854
 Metakentrin, 407, 408
 Metallic oxides, in electron microscope, 174, 185, 186
 Metals, emulsions of, 346, 347, 349, 353
 Metals, microradiographs of, 150
 Metals, mixtures of, by ultrasonics, 369
 Metals, under pressure, 334
 Metamyelocytes, 934
 Metaphase, 817
 Metastases, 995
 Metastases in cancer, 1028
 Metazoa, cells of, 873
 Metazoan parasites and cancer, 1019
 Mating behavior, in infusoria, 1166
 Medullated nerves, 1147
 Meinicke test, 1128
 Membrane effects of phosphatides, 1131
 Meteorological factors in evolution, 595
 Metathesis, 513
 Methanol, catalytic production of, 552, 553
 Methemoglobin, 557
 Methionine, 537
 Methyl iodide, 20, 21
 β -Methylamyl alcohol, 553
 2-methylbutanol, 553
 β -Methylbutyl alcohol, 553
 Methylcholanthrene, 590, 1021, 1023
 Methylcholanthrene and cancer, 1017
 Methylene blue, 111
 Methylene blue, adsorption of, 968
 Methylene iodide, 21
 Methylene iodide, spreading of, 18, 19, 22
 α -methylglucoside, 561
 2-methyl-1, 4-naphthoquinone, 734
 2-methylpentanol, 553
 2-methyl-3-phytyl-1,4-naphthoquinone, 734
 Metrazol, 1141
